POINTS FOR PRODUCERS.

Wheat Lands of the World.

The wheat area of the British Empire continues to grow. The latest published statistics show that 11,000 acres of wheat land in Great Britain were put to other use in 1910; but New Zealand balanced the loss by putting a like acreage under wheat, and India, Canada, and Australia added 4,018,000 acres to the wheat lands of the Empire. The wheat area of the United States increased by 2,482,000 acres, and that of Argentina by 1,029,999 acres. Russia reported the immense addition of 5,620,000 acres, but there appears to be some doubt whether this is not partly attributable to more complete statistics. Altogether, in the countries tabulated, there was an apparent net addition to the wheat area of rather more than 15,000,000 acres, or over 6 per cent. on the area returned in those countries in 1909. The wheat area in the British Empire increased, between 1891 and 1900, by three and a quarter million acres in Australia, six and a half million acres in Canada, and five and a quarter million acres in India, and declined during the same period by half a million acres in the United Kingdom and 80,000 acres in New Zealand.—*The Farmers' Advocate*.

Diseases Among Live Stock.

A number of cases of serious sickness among live stock have been reported to the Editor and through the Agricultural Bureau recently, and the assistance and advice of the Stock Department has immediately been solicited on behalf of the owners. In any case of urgency, however, it would be better if owners would communicate direct with the Chief Inspector of Stock by wire or letter, so that advice may be forthcoming without any unnecessary delay. The officers of the Stock Department are prepared at all times to give such advice as they can, gratis, to stockowners, farmers, and others, and reports of sickness should be sent as promptly as possible when disease appears among stock, or when sudden or suspicious deaths occur. Under the Stock Diseases Act owners are required to take very prompt action, as will be seen from the following reprint from the *Government Gazette*: —“Caution to stock owners.—Section 19 of the Stock Diseases Act of 1888 provides that—Every owner of diseased stock shall, within twenty-four hours from the time when such stock have been found to be diseased, forward by post in a prepaid letter notice thereof to the nearest inspector of stock, and to the Chief Inspector of Stock at Adelaide, and shall keep the diseased

stock from coming in contact with the stock belonging to other persons, under a penalty of not less than one pound nor exceeding twenty pounds for each and every day in which he shall neglect to give the required notice." Such answers to questions concerning stock troubles as are likely to be of interest will continue to appear in the inquiry column; and if any casual inquiries are received by the Editor they will be treated as heretofore; but stock owners are urged, in all cases of serious trouble and disease, to communicate with the Chief Inspector of Stock direct.

Agricultural Bureau Congress.

The twenty-fourth Annual Congress of the Agricultural Bureau of South Australia will be held at the School of Mines, North Terrace, Adelaide, on September 9th, 10th, and 11th. In last month's issue the attention of Hon. Secretaries of Branches was drawn to several matters in connection with the Congress, and arrangements for the gathering are now receiving the attention of officers of the Department of Agriculture. As usual, the agenda will include papers by members of Branches, in addition to addresses by the various experts attached to the Department. A novel feature will be a display of weeds and plants. Branches have been invited to forward to the Secretary to the Advisory Board, between the 2nd and 7th of September, any plants or weeds which they desire to have identified. These will be exhibited at the Congress, and the Botanist (Mr. J. M. Black) will give information regarding the various specimens and answer any questions.

The Value of Fallowing.

The July number of *The Agricultural Gazette of New South Wales* contains a striking illustration designed to call the attention of farmers to the value of fallowing. Accompanying the illustration are the following particulars of the general average in various districts of the 1911 wheat harvest, compared with that from experiment farms and farmers' experimental plots:—
"In the north—Average yield on north-western slopes, 8·52bush.; average yields on farmers' experiment plots (cultivated fallows), Quirindi, 34·08 bushels; Delungra, 28·8bush.; Pallamallawa, 29·02bush. In the west—Average yields, central tableland, 10·74bush.; central western slopes, 10·11 bushels; Bathurst experiment farm, 63 acres, Cleveland, Federation, and Bayah (short fallow), 23·5bush. In the south—Average yield on south-western slopes, 12·52bush.; average yield on farmers' experiment plots (cultivated fallows), Harden, 28·9bush.; Mimosa, 25·6bush.; Albury, 20·9 bushels; Wagga experiment farm, 68 acres, Federation wheat (cultivated fallow), 24·1bush."

World's Butter-Fat Record Broken.

With a record of 1,058·34lbs. of butter-fat produced in 365 days, Banostine Belle De Kol, a five-year-old Holstein-Friesian cow, owned by Dan Dimmick and Brother, becomes the new "queen of the dairy world" (says the *Breeders' Gazette*, Chicago). This wonderful cow produced during the year 27,404·4lbs. of milk, testing 3·86 per cent. fat. This means over 9galls. of milk per day, or enough to supply 36 families each with a quart of milk daily. If made into butter, her fat production would equal 1,322·925lbs. of butter, or over 3½lbs. per day for 365 days. This is all the more remarkable because it was made without her being dry at all before freshening. No other cow in the world has ever produced such an enormous amount of butter-fat in a yearly test, and only one other has ever exceeded Banostine's milk record. The official records of Banostine Belle De Kol are as follows:—

Length of Record.	Milk. Lbs.	Butter-Fat. Per cent.	Butter-Fat. Lbs.
7 days	672·5	3·67	24·697
30 days	2,828·0	3·50	98·987
60 days	5,505·0	3·53	194·033
90 days	7,856·8	3·61	283·543
7 days*	492·1	4·31	21·195
365 days	27,404·4	3·86	1,058·340

* This 7-day record was made eight months after freshening.

Banostine Belle De Kol was bred and developed by Dimmick and Brother. She is a strong, vigorous cow, of wonderful capacity, and will weigh in the neighborhood of 1,600lbs. She has given birth to three calves, this record having been made after the birth of the third calf. All of her calves have been heifers. The test was made under the careful supervision of the Dairy Department of the Ohio State University, America. The cow was tested by nine different persons, and watched at times day and night, so that the record is fully verified.

Fruit Production.

Particulars furnished by the Government Statist show that the area under fruit culture has been steadily increasing during the last five years. According to the latest returns 23,214 acres are now devoted to this purpose as against 22,410 acres in 1910-11. Below will be found the production of the chief kinds of fruit last season, the figures in parentheses being the production for the preceding year:—Apples, 583,860 (476,904) bushels; apricots, 165,982 (145,213) bushels; pears, 81,644 (80,868) bushels; oranges, 220,988 (153,464) bushels; lemons, 47,176 (44,799) bushels; cherries, 42,607 (45,085) bushels; plums, 106,758 (94,217) bushels; peaches and nectarines 80,315 (59,406) bushels.

Facts About Renmark.

The following particulars relating to the Renmark Irrigation Settlement are taken from *The Renmark Pioneer*:—Population (town and settlement), 2,500; area of settlement, 13,348 acres; dedicated commonage, 16,652 acres; area under irrigation, 5,156 acres; annual production, value £130,000; dried fruit pack, 1912, 2,200 tons; Irrigation Trust assessment, £200,000; Trust machinery and channels, £55,000; annual firewood consumption, 6,000 tons; annual water rate per acre, 1911, 25s.; Trust annual revenue, 1911, £8,082; annual Government loan repayment, £880; Trust D.C. assessment, 1911, £9,465; D.C. revenue (1s. rate, &c.), 1911, £1,307. Renmark fruitgrowers use annually about 5,000 tons of gypsum and large quantities of artificial fertilisers. Five irrigations are given annually. Chief products are sultanas, currants, raisins, oranges, apricots, peaches, pears, and olive oil, all of the highest quality. At Renmark and along the river generally, apples and all temperate fruit trees thrive and become productive much earlier than in colder districts dependent on the rainfall. Lucerne, maize, and all fodder plants do well, and wheat yields fair returns without irrigation. Renmark town population, 800; Renmark town valuation, £89,260; D.C. assessment, 1911, £3,852; D.C. revenue (rate 2s. 3d.), 1911, £463.

Fertility of the Soil.

Dr. A. D. Hall, M.A., F.R.S., Director of the Rothamsted Experimental Station, lectured recently before the Royal Institution on "The Fertility of the Soil," dealing with his subject particularly from the standpoint of the experimental work conducted at Rothamsted, Sir William Crookes being in the chair. Experiments at Rothamsted, said the lecturer, had shown that the addition of carbonaceous matter in the form of sugar to a Rothamsted plot poor in nitrogen had greatly increased the yield in barley. It was possible, Dr. Hall went on to show, that a production of over four quarters per acre of wheat could be maintained indefinitely by natural agencies alone, provided that the small annual losses of phosphoric acid and potash were replaced. The prospect of reducing the waste of highly intensive agriculture was not entirely hopeless. The losses were due to bacteria, which attacked nitrogen compounds and liberated nitrogen, but the researches of Dr. Russell and Dr. Hutchinson had shown that by putting the soil through various processes of partial sterilisation, such as heating or treatment with anti-septics like chloroform or toluene, certain organisms which checked the useful bacteria of the soil could be eliminated. Heating the soil to the temperature of boiling water for 10 hours would double its productivity, and the process had been found commercially profitable in the case of greenhouse soils. The market growers of cucumbers and tomatoes made up an exceptionally

rich soil of virgin loam and stable manure; but in a few years such a soil, while still enormously rich on analysis, became incapable of growing a profitable crop. Partial sterilisation enhanced the fertility of this soil by eliminating the injurious organisms. At present these processes had not been extended to the open field, but progress was being made in that direction, and gave some promise of a method by which ultimately the unseen fauna and flora of the soil would be domesticated, the useful races encouraged, and the noxious repressed, just as the larger flora and fauna had been reduced to the service of man since primitive man first turned from hunting to agriculture.

New Zealand Crops.

In publishing the average yield of field crops in New Zealand for the season 1911-12 the Dominion Government Statistician notes that the weather conditions experienced had a bad effect on root crops, but very favorably influenced the yield of cereal crops. The average yield per acre of the principal crops were:—Wheat, 36·69bush.; oats, 48·71bush.; barley, 39·65bush.; and potatoes, 5·13 tons.

Manuring Turnips.

In reference to the manuring of the turnip crop, including swedes, there is a significant table in a leaflet issued by the Irish Department of Agriculture. It gives the average results in yield and money value of the crop, after deducting the cost of manures, of 227 tests carried on in every county in Ireland during 10 years, farmyard manure being valued at 4s. per ton, artificials at their cost, and turnips at 8s. per ton. A dressing of 20 tons per acre of farmyard manure alone gave a greater yield, but less profit than half the quantity of manure, and when the addition of 4cwts. of superphosphate was made to 10 tons of farmyard manure, the yield was a little greater than that of 20 tons, while the profit from the dressing was largely increased. The further addition of 1cwt. of sulphate of ammonia brought the yield still higher, but reduced the profit; and the still further addition of 3cwts. of kainit brought the yield up to the maximum, but with another reduction in profit. When artificials were used alone, it is hardly necessary to say, a complete mixture proved most advantageous; but it is noteworthy that in 1911 every application without farmyard manure gave a greater profit than the corresponding one with the natural manure. Moreover, the highest average yield in a number of trials was 27 tons 12cwts. per acre, from the application of 6cwts. of superphosphate, 1½cwts. of sulphate of ammonia, and 4½cwts. of kainit, leaving a profit of £5 7s. 3d.; whereas 15 tons of farmyard manure, 4cwts. of superphosphate, 1cwt. of sulphate of ammonia, and 3cwts. of kainit gave only 24 tons 5cwts., and a profit of £2 5s. 7d. It is true that the residual

value of the dressing, including the farmyard manure, would be greater than that of the artificial alone, but where the natural manure is short, it is satisfactory to be able to secure a maximum crop without it, and at the same time a higher profit so far as the crop of the season is concerned.—*Agricultural Gazette*.

Maize for Forage Purposes.

The Essex Education Committee have made a report on the use of maize for forage purposes. The great need of a dairy district, particularly in a dry summer, is an adequate supply of succulent fodder. As maize is eminently adapted to meet this requirement, it was decided to test the relative cropping powers of some of the best-known Canadian and English varieties. The English varieties tested were White Tooth, Early Prolific, and Red Cob, the Canadian being Selected Leamington, Wood's Northern Dent, Eureka, White Pearl, and Superior Fodder. Owing to the lumpy condition of the soil when the seed was sown, the weights of forage obtained were comparatively small, the heaviest crop obtained being 13 tons 8cwts. per acre. Comparing the different varieties, White Tooth was superior to Red Cob, but the first three Canadian varieties—Selected Leamington, Wood's Northern Dent, and Eureka—were much superior to the English varieties. Not only was the weight per acre greater, but on their being chopped up they were found to be much more succulent.

Imports and Exports of Plants.

During the month of July 5,136bush. of fresh fruits, 2,834 bags of potatoes, 1,429 bags of onions, 27pkgs. vegetables, and 30pkgs. plants were inspected and admitted at Adelaide and Port Adelaide under the Vine, Fruit, and Vegetable Protection Act of 1885; 374bush. of bananas (chiefly over-ripe) were rejected. Under the Federal Commerce Act, 1,879 cases of fresh fruits, 99pkgs. of dried fruit, 108pkgs. preserved fruit, and 11pkgs. plants were exported to oversea markets during the same period. These were distributed as follows:—For South Africa, 1,000 cases apples, 99pkgs. dried fruit, and 1pkg. seeds; for London, 37 cases oranges; for India and East, 790 cases apples and 93pkgs. preserved fruit; for New Zealand, 52 cases citrus fruits, 15pkgs. preserved fruit, and 10pkgs. plants. Under the Federal Quarantine Act 1,354pkgs. plants, seeds, &c., were admitted from oversea sources.

INQUIRY DEPARTMENT.

Any questions relating to methods of agriculture, horticulture, viticulture, dairying, &c., diseases of stock and poultry, insect and fungoid pests, the export of produce, and similar subjects, will be referred to the Government experts, and replies will be published in these pages for the benefit of producers generally. The name and address of the inquirer must accompany each question. Inquiries received from the question-boxes established by Branches of the Agricultural Bureau will be similarly dealt with. All correspondence should be addressed to "The Editor, *The Journal of Agriculture*, Adelaide."

STOCK INQUIRIES.

(Replies supplied by Veterinaries of the Stock Department.)

Paralysis in Horse.

The Coomooroo Branch of the Agricultural Bureau ask the best treatment for a horse suffering from paralysis. The animal has, for a period of six weeks, been unable to move, and it appeared stiff in all its muscles.

Answer—The horse should be placed comfortably in slings, and one grain of strychnine mixed with a little sugar should be placed on the back of its tongue twice daily. Three times daily a teaspoonful of iodide of potassium should be given in the drinking water. Only a little hard feed should be given, the animal being fed on bran and, if possible, greenfeed.

Probable Case of Worms.

"E. O.," Leighton, had a young horse troubled with swellings under the belly just behind the girth. The sheath also swelled considerably and remained so for a few days at a time. The water was scanty, and the animal was tender under pressure on the loins. The owner desired to know the cause of the trouble and the remedy.

Answer—From the symptoms described, it is very probable that the young horse is badly affected with worms, as the dropsical conditions noted frequently result from their presence. It would be well to mix a level tablespoonful of a powder composed of the following twice a day in the food:—Epsom salts, 4ozs.; sulphate of iron, 2ozs.; flowers of sulphur, 2ozs.; powdered gentian root, 2ozs.; salt, 4ozs.; linseed meal, 1lb. Also keep the animal well fed and sheltered at night.

An Overdose of Kerosine.

The Petina Branch of the Agricultural Bureau reports the loss of three horses belonging to one of its members. The last of the animals to die was

a five-year-old gelding, which appeared to be in good condition, and had been worked right through seeding until it suddenly became ill. After it had been ill for three weeks it was given a drench of soda bicarbonate, and after that saltpetre. For three days it seemed all right, but then the trouble returned. It would attempt to feed in the morning, but commenced throwing its head up. A dose of linseed oil was administered, but apparently without any effect. This was followed by a dose consisting of a bottle of kerosine. The animal died soon after. A *post mortem* failed to reveal any rupture in the stomach, although the oil appeared to be outside the paunch, which, together with the intestines, was inflamed. The latter were surrounded by a watery fluid. The liver, lights, and heart seemed normal. In the paunch were found 10 grubs firmly fixed to the lining, and a small stone. About one-third of the paunch gave the appearance of having had the lining eaten off. No sand or worms were in the intestines.

Answer—It is to be feared that the horse died from the direct effects of an overdose of kerosine, a bottleful of that oil being far too much for a horse; the maximum dose should not exceed a wineglassful, and that should be well diluted with linseed oil or milk. The 10 grubs were no doubt “bots,” that is the larva of the fly which lays its eggs on the hair, and which develop in the horse’s stomach. The eating away of the stomach was probably a natural process which occurs after death, and is called *post mortem* digestion; but it must be remembered that one part of a horse’s stomach is white and the other pink; the latter is more active in digestion. It is impossible to form an opinion as to the cause of the illness of the horses from the few symptoms described, but it is probably due to a weakening fever which is prevalent at this time of the year, and it would be well to let the others have an ounce of Epsom salts mixed up in their food once a day for a week as a preventive. Give this quantity three times a day if they are ill; and if they are too much off their feed to eat it, they would drink it in half a bucket, or could be drenched with it in half a bottleful, of water.

POULTRY INQUIRIES.

Black Blotches on Roosters’ Combs.

“A.B.H.,” of Mount Cooper, asks for a remedy for large black blotches which have made their appearance on the combs of White and Black Leghorn roosters. The general health of the birds did not appear to be affected, and the spots did not seem to extend below the skin.

Answer—Without making an examination it is difficult to state the cause. Similar affections may be cured by bathing the comb with a 5 per cent. solution of carbolic acid, or of ordinary bluestone. If you have any formalin, apply daily a solution consisting of one part of formalin to nine parts of water.

THE POULTRY TICK.

By D. F. LAURIE, Government Poultry Expert and Lecturer.

[Paper read before the members of the Microscopical Society of South Australia, June 25th, 1912.]

(Continued from page 1258.)

DESCRIPTION OF THE TICK.

With the aid of the following illustrations it will be possible to make clear the main structural points, and also to elucidate many facts in the life history of the tick.

Plate 1.—Adult tick (female), ventral (underside) aspect, x 9. The ovate form of the body is clearly seen. The adult tick has four pairs of legs, and

PLATE 1.

PLATE 2.

its mouth parts (a) are so situated as to be invisible when viewed from above (dorsal view); (b) is the genital orifice, and (c) the anal ring. Each of the eight legs is furnished at the end with a double sickle-shaped claw, which enables it to cling tightly to any surface which offers the least irregularity. Thus it can climb woodwork, stone or brick walls, piping, and even thin wires. The legs have six segments, or articles, as they are termed. That nearest the body is the coxa, then come the trochanter, femur, tibia, protarsus, and

tarsus, always visible—and there may be additions. Articles 1 and 6 are generally referred to as coxa and tarsus, and the others by numbers. Large females measure up to 9mm. long by 5.8mm. broad. Four measured 8×5.5 , 8.5×5.2 , 8.0×5.5 , and 9×5.8 mm.

PLATE 3.

PLATE 4.

PLATE 5.

PLATE 6.

Plate 2.—Dorsal view of a medium-sized tick, x 7. This illustration shows a tick of medium size. Part of the integument forming the hood has been

thrown back to show the position of the mouth parts. This specimen is cleared and is semi-transparent. The cavity in which the mouth parts lie is called the camerostome, of which the hood forms the walls.

Plate 3.—Mouth parts of adult tick x 65. This enlarged view of the mouth parts gives excellent detail. Here can be seen clearly (a) the rostrum or hypostome—the biting mouth parts which the tick inserts into the skin of the host. (b.b.) the palpi (pedipalpi), which are leg-like appendages, one on each side of the rostrum or hypostome. These palpi are in constant motion and doubtless are extremely sensitive and serve as organs of sensation. (c) is the capitulum, the basal ring or false head.

PLATE 7.

Plate 4.—Mouth parts of adult tick x 65. This illustration shows very clearly the palpi and the rostrum with its mandibles or chelicerae, which are saw-toothed. This latter is the organ by which the tick cuts and tears the skin when preparing to feed. The bulb-like muscular processes of the mandibles are clearly visible.

Plate 5.—Details of mouth parts x 100. This clearly shows the closed maxilla or hypostome (also known as the radula or labium). The saw-tooth-like cutting apparatus is well shown.

Plate 6.—Mandibles of fullgrown tick x 60. These were dissected out by Mr. Poole, and serve to show clearly their formation as well as the lower end referred to in Plate 4.

Plate 7.—Mandibles of fullgrown tick x 100. This shows more detail of the structure of the mandibles. In the tick the mandibles or chelicerae consist of the (1) internal article ("median apophyses, or immovable finger"), and (2) the external article (external apophyses, or free movable finger).

THE LIFE CYCLE OF THE TICK.

Reference has been made to the prevalence of the tick in many parts, not only of this State, but of Australia generally. The following description, with the illustrations, will show the habits and character of the tick as well as the various stages of development.

PLATE 8.

Plate 8.—This piece of wood was in close contact with a post in a fowlhouse. The clusters of ticks of various sizes can be seen, and will give a good idea of what is commonly met with when examining infested premises. Tick can live for long periods without having recourse to fowls for food. I am inclined to think that in the absence of poultry the tick finds some other food; may, in fact, return to its original feeding habits (and consume decaying vegetable matter). I have had a pair of full-grown ticks in a bottle (2oz.) well corked, they lived for 18 months; but someone took the bottle, so that no further tests could be secured. If a number of ticks be put in a small jar they will soon die, unless the lid be perforated. This has happened on many occasions.

In examining old and disused poultry houses the ticks found show little vitality, and are apparently quite empty, and appear very flat. However, let some fowls roost in that house and the tick, with its uncanny sense of the presence of a fowl, will, as soon as dark speedily attack the bird.

FEEDING.

The tick feeds about once a month in hot weather, and requires that period in which to fully digest a meal. When gorging rapidly, Nuttall says they discharge clear fluid from the intercoxal spaces. During the growing period,

PLATE 9.

after digesting each meal, they undergo a moult, and cast their old skin and grow in the process until the adult stage is reached. A large jar containing a hundred or so specimens soon becomes littered with the accumulations of moulted skins. The adult female tick begins laying about a week after she

PLATE 10.

has fed. She deposits small batches of eggs (20 to 100), and may often be observed doing so on the sides of the specimen jar in which they are kept. She will lay several eggs in a minute. Nuttall reports that it took 10 months to rear tick from egg-stage to egg-stage.

Plate 9.—Shows a life-sized photograph of the full-grown tick, both dorsal and ventral views. Ticks take refuge in and infest the paling fences in the suburbs; they gradually extend along the fence for great distances, congregating in the vicinity of poultry houses which generally adjoin the fence. The adult tick will travel from an infested fence or old shed to a new poultry house. It, therefore, is absolutely necessary to seek them out and destroy them before the poultry can be considered safe.

HOSTS.

Plate 10.—Fowls are most commonly attacked by ticks. Turkeys, as a rule, roost on the tops of sheds and in high trees, and are seldom attacked. In suburban poultry yards where turkeys are placed to roost in an infected fowlhouse, they are also attacked and often succumb. *Plate 10* shows the head and neck of a common duck which was freely infested with larval ticks. Ducks often feed at night, and are generally restless and, as a rule, are not subject to attack.

Pigeons have been found infested with ticks but, as a rule, they are free from attack. Pigeons are very restless at night. Probably the pigeon as a host is not agreeable to the poultry tick here.

Lounsbury relates that he "once applied an adult to my arm, giving it free play under a pill box. It took hold and fed quite regularly, coming off engorged in about an hour; but its feast appeared to disagree with its digestion, for it soon turned black and decayed."

The human normal temperature is 98.4 (F.), that of fowls 106 (F.). This difference may have affected the tick in some way. Again, the chemical composition of the blood of man and of the fowl differ in their mineral salts. In Persia, strangers visiting the country, if bitten by the ticks, may become ill. The natives have acquired immunity. The trouble there is due no doubt to the spirochæte. The difference in body temperature and blood composition would favor progressive immunity.

Plate 11.—This shows a cockerel which was in parts literally encrusted with larval ticks in several stages of repletion. The bird was received from the country by a poulterer, who noticed the ticks when plucking the bird and after the left leg had been stripped. The specimen was placed in cold storage and held for some days in a temperature well below freezing point. This extreme cold apparently did not incommode the ticks, which were alive and well. Ticks do not always leave the host when the latter dies. Some ticks do, but the majority remain attached for several hours, even after the body has become quite cold.

PLATE 11.

Plate 12.—This shows part of the right side of the fowl shown in Plate 11. It will be noted that the ticks have congregated chiefly upon the bare skin (apteriæ), outside the feather tracts (pterylæ). There were many hundreds, perhaps thousands, of ticks on this fowl, which was in good condition for a

PLATE 12.

cockereel. The bird was bright and active, and showed none of the usual effects of the ticks, and yet he must have harbored them for some days.

Plate 13.—Micro-photograph of piece of skin of fowl shown in Plates 11 and 12, x 10. Examination of this plate reveals the fact that the larvæ have been feeding for some time, as they have assumed the oval shape with less prominent mouth parts.

PLATE 13.

PLATE 14.

Plate 14.—Micro-photograph of ovigerous full-sized female tick x 8. The remarkable feature of this specimen is the presence, clearly seen, of at least three eggs. The centre egg appears about to enter the ovipositor. With a low power (x 50) objective the ovipositor can be readily observed. It is the organ by means of which the eggs are extruded. By slightly irritating the part with a dissecting needle vigorous contractile movements can be noted. Fertilisation is effected by the male transferring spermatophores into the genital orifice of the female by means of his proboscis or rostrum.

(To be continued.)

FARM ANIMALS.

TREATMENT OF INJURIES (HORSE).

By OFFICERS OF THE STOCK DEPARTMENT.

The injuries to be dealt with in these notes are bruises and wounds, and some conditions in which both occur.

BRUISES.

Bruises happen both while at work and in the paddock—in the latter case from hitting up against low branches and so on, or rolling on hard and stony ground; and naturally the prominent parts, such as the poll, withers, and haunches suffer most. Bruises in the two former places are often the commencement of fistula. Kicks given in play or viciously are also a common cause of bruising, which is then generally on the legs, breast, or ribs. Bruises caused during work generally arise from pressure of badly-fitting harness or saddlery, and may be classed as collar or saddle galls.

The early symptoms are the same in all cases—tenderness, pain, swelling, at first hard, then gradually becoming soft and watery to the touch. These early symptoms are often overlooked, and the first noticed are a fluctuating swelling, with hair and skin being stripped. Where the skin is too tough to strip, as in the case of many saddle galls, the fluid inside changes in its nature and becomes hard and fibrous, resulting in a permanent lumpy swelling. In collar and saddle galls, where the pressure is intermittent, other changes occur in the structures beneath the skin, which at times render the treatment difficult. In the early stages of all bruises relief is obtained by frequent fomentations with water as hot as the hand can bear it, following this up with applications of tincture of arnica one part, methylated spirits twenty parts—roughly an ounce of the former to a pint bottle of the latter.

Space forbids the detailed treatment of collars and saddles being dealt with, but if they are properly *chambered* the horse will recover more rapidly at work than at rest. Should the swelling be soft and fluctuating the watery fluid must be let out by the use of a sharp lancet, at a point where it will drain well and the surgical wound will escape irritation from pressure. Should the fluid persistently re-form, the sac must be syringed out with a strong solution of Condyl's crystals—as much as will lie on a threepenny piece to two quarts of boiled water which is cooling down again. If the galls are

badly stripped, an application of neatsfoot oil and white lead, mixed to the consistency of cream, will often enable a horse to go on working and heal the sore at the same time.

When hard lumps have formed the surgeon's knife will effect a speedier and more effective cure than applications; though in some cases the lumps may be reduced by painting them daily with strong tincture of iodine.

WOUNDS.

Wounds among farm horses are generally stakes, cuts, tears, or a combination of the latter and bruises, as in broken knees. Stakes are the most dangerous, because dirt, which means harmful microbes, is carried deeply into tissues which are damaged by the forcible passage of the stake into them and rendered less able to deal with the invaders, often, too, serious damage is done which does not meet the eye.

Staked wounds must be constantly flushed out with a strong solution of Condyl's crystals or permanganate of potash, and whenever they occur in a position where a lower opening will give a thorough drainage, one should be made. If the wound is very large it may be plugged with antiseptic tow; but as a rule it is better left open. If, however, flies are troublesome it should be covered, and eucalyptus oil or some similar strong-smelling application put on to keep them off. Care must be taken that healing commences from the deepest part of the wound, as if the outer portion heals and encloses dirt, very serious results, such as blood poisoning and lockjaw, are likely to follow.

Cuts, if deep, must also be healed from the bottom, and unless they are very superficial it is, as a rule, not advisable to sew them up, as the swelling which occurs generally bursts the stitches out and makes a bigger scar than the original cut would have left, in addition to covering up dirt. If flaps of skin have to be held in place, a few strong pins, with horsehair or silk made into a figure of eight round them, will give a better hold than stitches.

The cuts must first be thoroughly cleaned out. When once this has been done, the fewer wet dressings they get the better they will heal. A good dry dressing is flowers of sulphur one part, boracic acid seven parts. If the cut is in a position in which a dry dressing persistently falls off, it may be made into an ointment with olive oil or vaseline. Tears, especially those caused by barbed wire, are the most difficult class of wound to heal. It is of little use trying to get rags of skin or tissue to heal on a tear, and they may be cut off at once, as any attempt to sew them on will only be disappointing and hinder healing. When the wound has been cleared of all bits of tissue and dirt—and the cleaning is helped by the use of soap and warm water—it should be dressed with a solution of Condyl's crystals, or similar dressing, and the dry dressing applied after. Often an artificial scab of Friar's Balsam and olive oil will protect places where too much of the

underlying tissues is exposed. When healing is slow and the edges of the wound remain angry-looking or slough away, an occasional painting with tincture of iodine will stimulate the healing process.

Wounds like broken knees, in which cuts, tears, and bruises are found together, require the preliminary thorough cleansing and the after treatment above described ; but at the same time the part must be kept as still as possible by means of splints and bandages, and the less wet dressing it gets the better.

When injuries such as those above described occur in the neighborhood of joints, the synovial membranes or oil bags of the joints are often opened or otherwise damaged, and the persistent flow of joint oil is frequently hard to check ; the measures which are often used to do so excite inflammation, and the joint is ruined altogether. A safe remedy in the farmer's hands is a paste made of starch or white of an egg seven parts, and so-called chloride of lime or bleaching powder, one part. A liberal application of this mixture will both stop the flow of oil and assist the healing.

BEE-KEEPING NOTES.

THE LEG STRUCTURE OF A WORKER.

By T. E. WHITELAW, Inspector of Apiaries.

An adult worker bee possesses three pairs of legs, which are attached to the muscular centre—the thorax. The anterior pair are joined to the pro-thorax ; the intermediate to the meso-thorax ; and the posterior to the meta-thorax.

A superficial examination of these legs reveals that these members, while serving the insect with the means of locomotion, also provides it with various contrivances suitable for the performance of its work. Structural adaptations are strongly in evidence which assists it to act as a conveyor of pollen from one flower to another.

Each leg is composed of nine segments. The first joint, the coxa, is round and short, forming the attachment to the thorax ; the second, the trochanter, has a somewhat similar appearance, and is followed by an elongated limb termed the femur, or thigh ; the fourth is the tibia, or shank ; the last five

joints are collectively called the tarsus, or foot, the first joint of which, the meta-tarsus, is larger than any of the other four. The terminal joint, though small, has an intricate structure comprising a pair of hooked claws with a cushion—the pulvillus—between them.

The thorax and the legs are densely covered with pubescence, forming a covering both protective and heat retaining. The hairs are various in shape and have special functions. Some are adapted for gathering and retaining liquid and pollen dust, others act as brushes and organs of touch.

Rough Diagram showing Anatomy of a Worker Leg.

I. Posterior leg, side next to body—A, coxa; B, trochanter; C, femur; D, tibia; E, metatarsus; F, angiculi; the reverse side of D, the corbicula.

II. Angiculi—A, angiculi; B, pulvillus.

III. Junction of tibia and metatarsus anterior leg—A, velum; B, antenna comb or sinus.

The posterior legs are the most interesting to examine. The joints nearest the body are to a large extent muscular. The outside surface of the tibia is concave, forming a hollow basket, or corbicula, fringed along its outer edge with long curved hairs. This is the receptacle in which the gathered pollen dust is conveyed to the hive.

The bottommost edge of the tibia, where it meets the meta-tarsus, has a row of teethlike hairs. Immediately below these, is a flat surface at one corner of the meta-tarsus, upon which they open and shut by means of the joint at the opposite corner. This apparatus is commonly known as the

wax pincers, and serves to manipulate the thin scales of wax generated by the wax glands on the ventral surface of the abdomen. It is also used for packing the pollen into the corbicula. This appliance is not found in the queen and drone, as neither of these insects are wax-producing.

The inside surface of the leg is covered with a series of stiff hairs arranged in rows, forming a perfect comb. The bee, when foraging for nectar and pollen, invariably has the underside of its body dusted with pollen grains from the anthers of the flowers. These grains are scraped from the hairs on its body by means of the comb, and carefully packed in the corbicula for conveyance to the hive. The long hairs fringing the corbicula serve to retain the pollen in position during its journey.

The terminal joint of the tarsus is furnished with a pair of hooked claws—the *anguiculi*—which are double-pointed. Between them is a cushion called the *pulvillus*. The claws are capable of ready movement in every direction, turning sideways or upwards if necessary. A tenacious grip is readily obtained on any surface of an ordinary nature. When, however, the insect comes in contact with a hard polished plane the claws turn upwards out of the way and the *pulvillus* comes into close contact with the surface. It is a soft membranous pad from which exudes an adhesive liquid derived from a glandular sacculus situated in the tarsus. By its means the insect can walk with ease, even on highly polished glass. That this adhesion is not produced by atmospheric pressure alone, is proved by the fact that flies continue to adhere to the interior of a vessel from which the air has been exhausted.

At the lower end of the tibia on the anterior pair of legs, a spine is found to which is attached the *velum*. On the adjacent edge of the *meta-tarsus*, beneath it, is a curved recess known as the *sinus*, the edge of which is composed of stiff, bristly hairs. The antennæ of the insect is cleaned by the operation of these appliances. The leg is brought up to the antennæ so that the latter lies securely in the *sinus*, the *velum* is pressed down on to it tightly, and the movement of the leg outwards removes every particle of dirt.

The intermediate legs possess no *velum* or *sinus*, but in the same position is a stiff pointed spur. The exact use of this article is debatable. By some persons it is supposed to be a lever for removing pollen pellets from the corbicula; others consider it simply as a collateral support, or as a wing cleaner.

The activity of a bee is well known. Its power of traction is equal to 20 times its own weight.

GRAPE VINE PRUNING FOR AMATEURS AND BEGINNERS.

By GEO. QUINN, Horticultural Instructor.

(Continued from page 1238, July Issue).

TRELLISED VINES.

From an economic point of view the trellising of grape vines is undertaken for the purpose of utilising in the fruit production the vigorous growth obtained from many varieties when planted in strong soils. Although, to a certain extent, this is an extension of the principle observed in retaining rods on bush-grown vines, it does not completely fulfil the same purposes, as some kinds, even when trellised, require to be rod-pruned if full crops of fruit are to be harvested from them.

Apart from the purely economic aspect, grape vines are often trellised for the purpose of covering unsightly buildings, shading sun-exposed walls, or ornamenting arbors, pergolas, &c.

It may truly be claimed that under favorable conditions of soil and climate nearly all vines, whether of rod or spur-pruned sorts, would yield much heavier crops if trellised; but the initial cost of the trellising is considerable, and this fact often deters the owners from thus training the plants. On the other hand, the impediment to cross tillage of the land—so desirable under the dry conditions prevailing in many parts of Australia—is an argument against the use of trellises.

Assuming, therefore, that trellising is done for the purpose of securing growth and fruit over all of the space afforded by any such structure, it becomes necessary to follow a systematic plan in the training of the vine which shall secure this end over the longest possible period of years.

Fig. 16 fairly represents the too common lack of system as displayed in many of the vines grown by amateurs for the purpose of covering an unsightly wall. In dealing with observed facts in the growth of plants which underlie the principles governing pruning, attention has been drawn to an unvarying superiority enjoyed by the topmost shoots in receiving sap. Whilst this cannot be too strongly emphasized in respect to shoots on the grape vine, it must be also admitted that trellising affords a means whereby this advantage—which in standard trees, or bush vines, is secured by certain

parts—may be minimised and distributed to all with an evenness not possible under any other method of training. This leads us to the expression of the one great principle upon which the most successful trellising of the grape vine

Fig. 16.—A Vine Trellised, but not Systematically Trained. An Ineffective Method of Covering Wall with Vines.

is based, and that is, *the permanent parts of the plant must be so arranged that all annual growths (fruit shoots) may arise from a common level.* This means, therefore, that the permanent arms—if more than one be used—on any given vine shall be trained, not only horizontally, but on the same level above the soil. By most persons who trellis grape vines this is a principle which is either

Fig. 17.—A Good Intention Gone Astray.

not fully grasped or is allowed to become overridden by a desire to secure growth and fruit over too large an area in the early stages of training the plant. The trellising depicted in Fig. 17 is a good illustration in point. Here the pruner of a number of the vines evidently started correctly, but had grown "weary in well-doing" and departed from the first principle involved, with the invariable result that the annual growths now arise here and there in haphazard fashion about the trellis, with the ever-increasing tendency to become more and more abundant on the upper branches of each plant as those below are robbed of sap and starved out of existence. This result is not arrived at until a few years after the vine begins to bear. Let it be trained and hacked about never so unskilfully, the natural prolificacy of bearing displayed by the grape vine appears to reward the pruner, and sound the praises of his methods for a time. The day of reckoning, however, is bound to follow in the shape of long naked limbs, crowned with a crop of fruiting wood at the very topmost positions only.

Wherever a high trellis has to be covered, as is attempted in Fig. 17, several tiers of separate vines should be planted in regular series one above the other, so that the permanent arms on any given plant emerge at the same level from their parent stem.

There are points common to all trellised vines, which have been noted already in respect to bush vines, probably the most important being the reduction of overgrown secondary arms per medium of the utilisation of water-shoots.

In training the main arms, experience shows that it is false economy to twist them around wires, as such an act ultimately results in the necessity for removing the wire from the swollen folds of the arm, or constriction of the sap vessels will take place to an injurious extent. The pruner must distinguish between twisting the temporary cane, which is left for fruit production only, and the permanent cane retained for the extension of the main arm. Authorities agree that in no case should spurs or rods be retained which arise within about a foot of the bend or angle made where the vertical stem merges off into the horizontal main arm or arms, as the position is one of considerable advantage for receiving sap, and any such shoot almost invariably robs the growths situate farther along the main arm.

THE SPALIER.

This is the term applied to a trellised grape vine on which a permanent arm is trained out from the stem on each side and in the same plane, each pair—if more than one pair—being on the same level. Some forms of spaliers have several pairs of such arms, each set of which emerges at regular distances along the main stem—one above the other. Owing, however, to the great and constant care required to regulate the activity of vegetation in the arms thus set at varying heights, such a form is not recommended for use, excepting to such persons who may desire to follow the work of trellising purely as a

hobby, and devote considerable time to pinching back shoots in summer. The best and most simple type to follow in spalier training is to permit one vertical stem only and one pair of horizontal arms—be they short or long—to each vine. To attain this end the newly planted vine is, as recommended for the bush vine, pruned back to a single spur of one or two buds, with a view to inducing at least one very strong shoot to arise during the ensuing summer. This shoot should be secured to a stake as it ascends.

Fig. 18.—Forming Bordelais Spalier; Fourth Winter Pruning.

Fig. 19.—Bordelais Spalier (Vine of Moderate Strength).

There are two types of spaliers suggested for use here in Australia, viz., the *Bordelais* or *Bordeaux spalier*, which possesses a pair of extremely short main arms, resembling the prongs of a fork, and the *Thomery spalier* (named after a district near Paris), in which a pair of arms is, with the exception of on a few varieties, permitted to extend much farther away from the parent stem, but in a horizontal position.

The Bordelais Spalier—Figs. 18, 19, 20.—This form has been recommended by our Government Viticulturist (Professor A. J. Perkins) as suitable for adoption in connection with the growth of certain wine grapes which need rod-pruning, such as Pinot, Carbernet Sauvignan, Shiraz, &c., when planted

in comparatively poor soils. This form is suited to a cheap trellis of two wires; and the authority quoted above advocates 12in. to 15in. above the soil as a suitable height for the bottom one, to which the annual fruiting canes or rods are tied, and a second wire about 20in. above the lower one, to support the growing shoots. The type consists of a stem about 10in. high, on each side of which in the direction of the wire is one short main branch bearing each, according to the strength of the vine, either one rod and a spur (Fig. 18), or two rods and two spurs (Fig. 20.)

The vine is trained by pruning to one spur at the second winter season the shoot which arises the first summer after planting, and this at the requisite height to form the stem. The pruner at the same time sees that the two topmost buds are on opposite sides and face the wires. The following summer these two upper buds are encouraged to make good shoots. Next winter both of these are pruned as spurs, with from three to six buds each, thus forming the fork-like main arms, and the resulting growth should give at least

Fig. 20.—Bordelais Spalier (with Four Rods and Four Spurs ; Vine Strong).

two good canes from each arm. One of each of these is pruned to a spur for wood production purposes and the remaining two are made into canes for fruit-bearing in the coming summer (see Fig. 18). *The vine is now formed, and the annual pruning consists of suppressing the previous year's rods, removing all water-shoots and suckers, and converting two shoots of the previous summer's growth to a spur and rod respectively on each main arm ;* or, as previously stated, strong vines may carry two rods and two spurs on each side, as shown in Fig. 20. In all such operations the spur, being reserved for wood production, necessarily regulates the framework of the vine and is in part comparatively permanent in character, whilst the rod is used for a temporary purpose, viz., fruit-bearing. The spur, therefore, to prevent undue extension, should be made from the cane situate lowest down upon the main arm in the direction of the main stem. In the course of time, even with the constant exercise of this precaution, the main arms must become exaggerated in length or impoverished with old scars. The pruner must then use his judgment in securing their renewal by means of suitably placed water-shoots, as described heretofore.

WATTLE GROWING.

PLANTING AND TREATMENT OF SEED.

By WALTER GILL, Conservator of Forests.

The wattle of which particulars are here given is the golden wattle (*Acacia pycnantha*). The black wattle (*Acacia decurrens*) is quite unsuited for the northern and western districts of this State.

REARING WITHOUT CULTIVATION.

The golden wattle is reared in two ways—with and without cultivation—and the treatment of the seed prior to sowing largely depends upon which of these is adopted. On any estate there may be patches of land in open forest country rather too rough for cultivation, and covered with undergrowth, which the owner may decide to use for wattle-growing. The undergrowth on such land must of course first be grubbed, and when the grasstree, hakea, acacia, and other bushes are dry enough to run a fire, wattle seed can be scattered broadcast. The firing of the grubbed bushes and ordinary rubbish usually found in open forest country creates a suitable seedbed for the seed, which at the same time it prepares for germination by cracking its tough skin. Considerable areas of wattles have been successfully developed in this way. The limited number of trees occurring on a good deal of light timbered country are a benefit to the wattles, as they shelter them from frost in winter and sun scald in summer. Some trees could be rung if they were too thick, and would still continue to yield some shelter.

The wattle is a shrub which demands a certain amount of shelter to grow to the best advantage, and, though opinions adverse to this view are held by some, the writer has been informed by one of the most experienced bark buyers in the State that the best bark is usually obtained from wattles grown under the shelter of larger trees. If the undergrowth should be too thin to give a uniform result over the whole area, it may be sown and burnt in patches, and the wattles can either be left to spread gradually, or the clear patches can be filled up by other methods, such as spading in a few seed in patches at about 8ft. distant.

TREATMENT OF SEED FOR CULTIVATED AREAS.

All things considered, the best way to treat seed for sowing on cultivated ground is to place it in a vessel, pour water almost boiling upon it, and leave it to soak for several days. It should then be kept damp in a bag till swelling takes place. It is a good plan to mix sand with the seed, as this avoids sowing too thickly, which is an error generally made, and results in much needless labor in thinning the wattles later on. About half a bushel of sand to the pound of seed has been recommended as a suitable quantity by some; but the individual grower will easily judge of this for himself after a brief trial. The quantity of seed per acre may be half a pound, or thereabouts. It can be obtained from any of the city nurserymen.

CULTIVATION OF THE LAND.

Ploughing the land to a depth of 6 in. or thereabouts is enough, and a good harrowing will prepare it sufficiently for broadcasting the wattle seed, after which it can be lightly covered either by a light set of harrows if the land be rough, or by brush harrows if sandy, as the seed only needs covering about an inch.

The Forest Department has lately secured remarkably good results in rough ironstone country in the Kuitpo Forest, Meadows district, by broadcasting in a new plantation, over land just roughly ploughed with a stump-jump plough in the usual way for tree-planting; showing that excessive care is not needed if conditions are suitable.

TIME FOR SOWING.

The seed may be sown during the winter months in light warm soils, but in heavier land, especially when the soil gets constantly saturated and thus kept in a cold state, sowing should be left till early spring warms the ground.

SUITABLE CONDITIONS.

The golden wattle requires a fair rainfall and good ironstone country to produce the best bark. The ironstone country in the Mount Lofty Ranges is unsurpassed in its capacity for producing the best bark which comes into the Adelaide market. As a rule limestone country does not suit the golden wattle, and a great deal of poor sandy country, though it will grow wattles of fair size and imposing appearance, will not grow bark containing sufficient tannic acid to pay stripping and cartage and yield a profit.

POULTRY NOTES.

By D. F. LAURIE, Poultry Expert and Lecturer.

OPERATIONS FOR AUGUST.

HATCHING.

This month should see the bulk of the heavy breed hatching in full swing. As a rule, except for competition breeding, the middle of September is late for the heavy breeds. August may be looked upon as the busy season for all breeds, as many only begin hatching the light breeds at this time.

Broody Hens.—Before allowing these to sit upon eggs they should be well dressed with insect powder in order to destroy all vermin. Do not use kerosine, oil, or any strong-smelling substance, as their use will prove fatal to the embryo. It is better to remove a broody hen or turkey at night. Invert a box (ventilated) over the nest so as to keep the hen dark for a day or two, so that she may settle down.

The Nest should be made upon the ground, as in that position there is less evaporation of the contents of the egg. Of course, many successful hatches take place where the eggs are on a wall or in suspended nests. The ground, however, has been proved to be the proper place. Make a shallow depression and line it with clean short straw or dry grass. Do not give the hen too many eggs—less in cold weather than when it is warmer. Wash all dirty eggs and mark them in ink. Make a record of date when set, number of eggs, and any other particulars, such as breed, strain, pen number, &c. Examine the nest frequently, and if an egg is broken, remove the debris and sponge any soiled eggs with clean warm water and dry with a clean soft cloth. Apply insect powder to both hen and nest as required.

Testing the Eggs.—From the fifth to seventh day the eggs may be tested to ascertain if they are fertile. The simplest method is as follows :—In the centre of a piece of cardboard measuring about 8 in. square, cut out an egg-shaped hole, rather smaller in size than an average egg. Procure an ordinary “Bismarck” reading lamp without shade and attachments. Carefully remove, at night, all the eggs from under the hen and place in a warmly-lined basket (an old felt hat is excellent). Hold each egg in turn tightly against the hole in the cardboard and then close to the lamp. The light, not intercepted by the cardboard, passes through the egg. If infertile, the egg will appear clear; if fertile, the small embryo will be clearly visible, and generally has the appearance of a small-bodied, long-legged, reddish spider; frequent undulating movements may be observed. Should a ring of red appear it is a sign of rupture. If a black spot be noticed, without any

free movement, it is a dead germ. These eggs can be discarded. The clear infertile eggs are quite good for cooking, there is no life in them; in fact they are superior to the average egg which is only marketed from the farm once a fortnight and arrives at your table a fortnight later. Return the fertile eggs to the hen without undue delay, so that they are not chilled.

Incubation.—Hen's eggs take from 20 to 21 days to incubate; duck's eggs from 27 to 28 days. The sitting hen should not be disturbed at all about hatching time. The beginner is often anxious to know results, and any interference will worry the hen, who at this time is in an anxious frame of mind. If undisturbed the hen will, as a rule, bring off a good clutch and will remove them when the proper time arrives.

Feeding and Water.—Feed sitting hens on grain, but do not feed them on the nest. Provide a receptacle of clean fresh water near at hand, as sitting birds are frequently thirsty. They should always be encouraged to leave their nests daily. They can then feed, dust themselves, &c., and the eggs are also aired. In mild weather a hen may safely leave her eggs exposed for an hour or more. Provide, in a dry corner, a dust bath of dry dust and wood ashes.

THE INCUBATOR.

There are several reliable incubators on the market. Breeders will be well advised if they follow carefully the instructions issued by the makers.

Incubator-room.—Any well aired room or cellar will do for an incubator to stand in. It is a bad practice to have them in living rooms where there is a fire by day and none during the late hours of night and early morning, as there will be great variations in temperature. A cheap and satisfactory room can be built underground, half underground, or overground. It may be built of hardwood slabs and the roof covered with earth a couple of feet in thickness. Ventilate the roof with an exhaust pipe fitted with a "Hit-and-miss" ventilator. A hard earthen floor will do. More elaborate structures can be erected if desired.

ESSENTIALS TO SUCCESS.

The Eggs.—Let your aim be to hatch only those eggs which are laid by proved hens, whether as layers, for exhibition, or for table. Reject all oversized and all very small eggs, and also those which have rough or misshapen shells. Wash in clean water and dry with a clean cloth any dirty-shelled eggs.

The Thermometer.—Much loss and disappointment occurs through the use of faulty and incorrect thermometers. The modern rage for the cheap generally ends in acquiring the nasty. Have your thermometers tested by a reliable man.

Lamps and Kerosine.—The lamps should be cleaned each day and filled to about seven-eighths of their capacity. Use only the best brand of kerosine, and keep the wick carefully trimmed so that a slightly rounded flame results.

Air and Moisture.—The eggs should be turned each day, morning and evening—it is not necessary to turn them exactly half round. Eggs in a tank machine require longer periods of airing than those in a hot air machine. In tank machines, fill the water pans from the start. In dry weather or during long continued dry frosty weather, a wet sponge should be placed under the egg tray in hot air machines.

Dry the Chicks.—Leave chicks and ducklings in the machine until quite dry; on removal keep them warm for at least 30 hours, and do not feed.

FOODS AND FEEDING.

Poultry-breeders would do better, in many cases, if they paid more attention to this subject. In the majority of cases the birds get but little variety, and consequently become stale. Space does not admit of lengthy explanations. The average poultry owner in this State gives his poultry a feed of wheat twice a day and lets them forage for the balance. The average fancier or utility man gives mash in the morning made of bran and pollard, greenfood midday, and wheat at night. Here there is little variety. All cereals are deficient in mineral salts, which are of the utmost importance in feeding poultry. Bran and pollard are both mill by-products of wheat, and with these in the morning and wheat at night there is no variety, although it is better than wheat only. As an egg producer wheat varies according to its composition. Bran and pollard contain many of the valuable food elements rejected in the process of milling flour. Wheat is deficient in fat. Oats are, when wellgrown and plump, excellent for fowls, especially in winter. They contain more fat and less starch than wheat. Oats may be fed freely. Barley is only useful as a change. Barley meal and ground oats are excellent for fattening table poultry. Peas are rich in protein or flesh-making compounds, but are poor in fats. They are, however, excellent for occasional winter use. Maize is generally too expensive to use, but as it is rich in fats it can be used to great advantage in the cold weather and as an agreeable change of grain.

An abundant supply of greenfood, such as rape, kail, lucerne, mustard, &c., should be provided, as from these are obtained the valuable mineral salts, &c., lacking in grain. Give as much variety as you can as regards the grain portion.

The mash should be made of bran, one part, scalded with hot water or hot meat meal soup, and allowed to stand for 20 minutes; then add twice as much pollard, and rub the bran dry with this until you have a crumbly, flaky mass. Mix the mash with the hands—this is the key to successful feeding. Feed the mash in clean earthenware or enamelled dishes; do not throw it upon the ground.

Scatter the grain in clean straw, so that the birds must scratch and work hard to obtain a share. The exercise keeps them warm, healthy, and occupied.

EGG-LAYING COMPETITIONS.

TWELVE MONTHS' TEST.

ROSEWORTHY.

[Started April 1st, 1912, and to terminate March 31st, 1913.]

NOTES ON EGG-LAYING COMPETITIONS.

ROSEWORTHY AND KYBYBOLITE POULTRY STATIONS.

The month of July is always a time of great anxiety in connection with laying competitions. The weather is the controlling factor, and this year it has been more trying than usual. From the end of July onwards steady progress and good laying may be expected until the crucial time arrives when the merits of any particular pen of birds receives its test. Well-bred, well-reared pullets will continue to yield a satisfactory supply of eggs, the lesser lights will fail. It is too early to say more than that the prospects of fine general averages are promising.

ROSEWORTHY.

The Superintendent reports—The general condition of the birds is good, and nearly all have that bright appearance we are so anxious to see after the critical period which is usual during the months of June and July. Some few of the birds are in a light moult. These instances occur as individual ones in different pens, and consequently are to be regretted more so than if the whole of the birds in such pens were in moult. In the latter case it could be the better understood, but where the birds moult one at a time at different intervals, extending over a period of four months, it is very difficult to follow the system of breeding and selection adopted by some breeders. While this system is continued it will be impossible to obtain even fair weekly scores from pens so selected; but while the general averages could be improved upon, largely by improved methods of selecting the layers, it is pleasing to note that the laying has been fairly well maintained, although on a lower level than is desired. The number laid during July was as follows:—Section 1, light breeds, 6,661; section 2, heavy breeds, 2,283; section 3, scratching sheds, 1,270. Through some reason which has not yet been determined, a serious falling off occurred during the month. Section 2 has produced 22 broodies. The health of all the birds has been good; no deaths occurred. The temperatures for the month have been as follows:—Average maximum, 51.1°; average minimum, 35.7°. Rainfall, 1.68in. There was wind on 27 days; a feature of this was that it blew from the north-west on 13 days and from the north-east on nine days.

KYBYBOLITE.

The Superintendent reports—The general health has been good; no deaths occurred, though there were a couple of cases of cramp. The laying has been good, with a slight falling off towards the end of the month. This is due no doubt to the frosts and cold. Total eggs laid were—Section 1, 8,421; section 2, 1,190. Out of 11 days we had seven frosts. The minimum temperature was 28°, with a maximum of 60°. Wind was registered on 20 days, many of which were very cold.

D. F. LAURIE, Poultry Expert and Lecturer.

GARDENING IN THE HILLS.

THE VALUE OF LIME.

(Lecture by the DIRECTOR OF AGRICULTURE.)

The Director of Agriculture (Mr. Wm. Lowrie, M.A., B.Sc.) recently addressed the members of the Campbelltown Branch of the Fruitgrowers and Market Gardeners' Association on various essentials connected with market gardening, and emphasized the value of lime as a means of increasing the fertility of the soil. In the course of his remarks he pointed out that the market gardener depended largely for his measure of success on the quality of his produce. Forethought in planning and carrying out a scheme to have garden commodities ready a little earlier or a little later than the period at which the market was glutted, brought its own reward; but quality was always an essential factor in securing readiness of sale, and the best prices available at the time. Heavy yields had an important bearing on the commercial success of the grower, but excess of bulk was frequently largely discounted through lack of quality. Thus it was necessary for the gardener and fruit-grower to aim at the production of the heaviest yields combined with highest quality.

Factors which made for this ideal were—(1) The careful selection of seed and of the most improved varieties of plants and trees suitable for the climate and the special purposes in view; and (2) the thorough, systematic, and intelligent tillage amendment and manuring of the land. The value of fertile market gardening land within easy reach of the markets was high, so that it was incumbent on the occupier to make it yield to the fullest capacity consistent with the maintenance of soil fertility. And this could only be accomplished by husbanding resources, and by the application of controlling factors such as those which conduced to the continuous vigorous activity of plant life during the period of growth. Any check, or series of checks, from excess or lack of moisture, imperfect tillage, and injudicious manuring, affected the ultimate yields, and told its tale in the range of quality. The market gardener was, or should be, the master of an art—he was the apostle of intense culture—and he was bound to force the pace or fail in competition; or, if owner of the land, be satisfied with less returns than his property was capable of producing.

THE NEED FOR LIME.

The value of lime as a means of increasing the fertility of the soil had almost completely been lost sight of; yet it was a most important factor in ensuring the greatest success on some of the areas in that district, and over the major portion of the market gardening land in the hills, where the rainfall was heavier. Those who broke up the rich alluvial flats in the first place found a wealth of fertility. As a consequence they had been able to go on cropping the land for many years without feeling the need for lime. That time had now arrived, and the sooner the position was realised the better it would be for the land and for the pockets of the producers. Growers, anxious to get the heaviest crops in the quickest time, had dressed the land heavily with stable manure season after season.

They had, however, apparently failed to realise some fundamental facts. Before the benefit of the fertiliser could be obtained it was necessary that it should decompose. That process proceeded through the agency of nitrifying ferments—microscopic organisms. If the conditions were favorable, these ferments performed their work of disintegration rapidly, but if the conditions were unfavorable the decomposition was not effected to anything like the same degree, and there remained in the soil organic acids which made it sour. As a rule, sour land was considered to be wet, cold land, which had become waterlogged and was difficult to aerate.

In the case of the market gardeners, they might have good under drainage and work their land thoroughly and frequently, but if they failed to put into the soil the elements which ensured the continuous and proper activity of the nitrifying ferments they must expect it inevitably to become sour. The farmyard manure applied did not yield up its nitrogen through decomposition sufficiently quickly unless stimulated by lime.

The use of lime was one of the means, the most ancient, of improving the fertility of land; but with so much attention being given to phosphates, this traditional amendment had been overlooked. "Lime sweetens the soil," was a trite saying, but a true one. But lime did more than that. It undoubtedly helped materially to make stiff land more porous and open, but that was only one of its influences.

Another equally, if not more important influence, was that it increased the activity of the nitrifying ferments. It was also a means of supplying indirectly potash to the land. These did not represent all the benefits derived from the use of lime, but they were sufficient to justify him in directing their attention to it and strongly urging them to give it a thorough trial.

They must not expect any much resultant good in the first year. Time was required for the lime to do its work, and it might be two, three, and even four years before they would see the full effects of a dressing. Lime offered a base for nitric acid, formed in the soils as the product of ferment activity, and generally it neutralised acidity of soils, producing most favorable

conditions for ferment and plant life. It was, therefore, a desirable soil stimulant where heavy rain and continuous cropping had leached most of the lime out of the land. It was a matter of primary importance to gardeners to replenish supplies, and the reason this had not already been generally done was probably partly due to the relatively high cost, and the common belief that it was useful only for ameliorating the physical texture.

FREQUENT DRESSINGS PROFITABLE.

Supplies at a reasonable figure were now procurable from merchants, who had awakened to the knowledge that there must come a good demand for agricultural lime in certain districts. Quicklime (not carbonate of lime) could be purchased at 23s. 10d. a ton, bags extra ; and lime ash, which contained about 70 per cent. of lime and 30 per cent. of wood ash and sand, at 1s. 6d. a bag. Hydrated lime was quoted at 2s. 3d. a bag, on trucks. He contended that it would pay well to apply frequent dressings of lime at those prices.

It was worth bearing in mind that part of the super. or other phosphates, especially soluble phosphates, which they introduced to the soil, were bound up fast and insolubly in the form of phosphate of iron and phosphate of alumina. The iron seized upon the phosphates, entered into combination with them, and formed an insoluble salt. There was no better method of breaking up that combination and of getting the benefit of the plant foods contained in it than by the utilisation of quicklime. If there was a deficiency of lime in the soil it was utterly impossible to reap the utmost advantage from the artificial and other fertilisers. Weight for weight, quicklime, of course, was the best to apply, because there was more lime in it. There was the same amount of calcium oxide in 56lbs. of quicklime as there was in 160lbs. of carbonate of lime.

SEA SHELLS FROM KANGAROO ISLAND.

Some experiments were being carried out with shells from the Spit, near Kingscote, Kangaroo Island, and he believed these would prove so successful that they would lead to a great demand of available supplies for use in orchards and gardens where lime was required. Samples of the shells, when analysed, had revealed 94 per cent. of carbonate of lime, equal to about 5 lbs. of quicklime. Supplies of the shells could be secured for 13s. a ton, compared with 26s. a ton for quicklime. By acting in co-operation the producers could purchase an oil engine and crushing plant for, say £300, instal it on the Spit, and have the shells crushed there before forwarding. The shells could be applied to the land as they were, but their action would be much more rapid if they were first crushed to powder.

Of course, if the price of quicklime fell to £1 a ton there would not be any need to go to Kangaroo Island for sea shells, and as things were the limeburners

had a good case, but he doubted, however, whether there could be such an appreciable lowering of price as that, in view of the costs to the burner.

THE QUANTITY TO APPLY.

A fair dressing of lime would be about one ton of quicklime per acre, or, say, two tons of shells per acre. However, applications of 5cwts. to 7cwts. of quicklime at frequent intervals would meet requirements probably, if one heavy dressing had been applied in the first instance. For all-round general usefulness gypsum was far behind carbonate of lime. As a means of opening up the soil its value was relatively small, and it was not comparable with quicklime as an agency in increasing the activity of the nitrifying ferments.

In laying out an orchard the tilling and all other essential work should be done with absolute thoroughness right from the start. He would not advise putting lime in the holes when planting trees, but it would be well to work some in periodically on the surface afterwards, as it would undoubtedly induce the roots to lead out. Like potash, lime increased the sweetness of a lot of the fruits, especially oranges, and made them more palatable.

UNDER DRAINAGE.

He advocated under drainage as a means by which increased returns might be obtained from such market gardening land as became water-logged and spuey in winter. It was well known that crops grown on such land were the first to show the effect of dry conditions during the summer. Paradoxical though it sounded, the removal of the excessive moisture in the winter would result in the better retention of moisture in the summer. The existence of under-drains allowed the water to go down, and as it percolated through it was followed by the air. Thus, the soil was aerated, and deeper rooting habits were cultivated. When the soil was water-logged air was excluded, and roots remained near the surface, to feel the pinch of the first dry spell.

VINEYARD PRODUCTION, 1911-12.

The Government Statistician has issued the official return of the yields of the vineyards of the State for the past year. It was expected that the dryness of the season would seriously affect the vintage, but it is satisfactory to report that while there is a decrease of 548,461 gallons, or 16 per cent., on the previous vintage, the average for the last five seasons has been exceeded by 90,460 gallons. The yield was 2,921,597 (3,470,058) gallons. A large quantity of the wine annually made is afterwards distilled for the production of brandy.

STATEMENT OF AREA AND PRODUCTION OF VINEYARDS FOR THE FIVE SEASONS, 1907-8 TO 1911-12.

Seasons.	Total Area (bearing and not bearing).	Grapes Gathered.		Wine made.	Currants Dried.	Raisins Dried.
		Total.	Average per Acre of Bearing Age.			
	Acres.	Tons.	Tons.	Gallons.	Cwts.	Cwts.
1907-8	21,080	26,005	1.34	2,061,987	19,958	21,488
1908-9	22,031	34,697	1.73	3,132,247	24,449	28,007
1909-10	22,441	31,040	1.52	2,569,797	36,052	27,808
1910-11	22,952	36,861	1.81	3,470,058	40,261	34,745
1911-12	23,986	34,591	1.67	2,921,597	46,695	31,651
Average for five seasons	22,498	32,639	1.62	2,831,137	33,483	29,940

EXPORTS OF WINE.

A substantial export trade in wine and brandy made from wine is carried on with the other Commonwealth States; but as it is not recorded, the following statement is confined to the exports to countries beyond the Commonwealth.

Wine.	Exports for Years —				
	1907.	1908.	1909.	1910.	1911.
Gallons	353,381	320,438	520,269	449,673	585,603
Value £	35,989	32,631	53,325	48,114	66,617

VALUE OF PRODUCTION.

The following statement shows the estimated value of vineyard production (grapes for table, currants, raisins, and wine made) for the seasons 1907-8 to 1911-12 and the percentage of value to total value of all crops, and the average value per acre of vines of bearing age.

Seasons.	Total Value.	Value of Vineyard Production.					
		Percentage to Total Value of all Crops.	Value per Acre of Vines of Bearing Age.				
	£	£	s.	d.	£	s.	d.
1907-8	384,344	5	19	3	19	15	11
1908-9	403,153	5	13	3	20	2	5
1909-10	398,426	5	6	10	19	11	6
1910-11	585,285	8	2	1	28	14	9
1911-12	578,504	7	11	7	27	18	10
Average five seasons	469,942	6	11	0	23	5	10

EXTRACTS FROM TRADE COMMISSIONER'S REPORTS.

The following is an extract from the Trade Commissioner's Report, dated London, June 14th :—

BRITISH DAIRY FARMERS' SCOTTISH TRIP.

At the invitation of the above body, I joined them in a tour of inspection of the leading stud stock farms, butter and cheese and margarine factories, experimental farms, and abattoirs, situated in the various parts of Scotland.

DAIRYING.

In the part of the country we visited one could not help being impressed with the almost general use of the Ayrshire breed of cattle for milk producing. This type of cattle is being built up to a much bigger and heavier boned beast than we know in Australia, by systematic breeding. Different counties, however, favor other breeds, and during the tour, herds of Galloway, Aberdeen, and Shorthorns were inspected. The first-named breed is an exceptionally fine carcass beast.

Cheese-making is carried on very extensively, as well as the sale of milk direct to the large towns. The climatic conditions are such that cheese can be cured without resorting to artificial means. The turning shelves employed in curing-rooms are ingeniously constructed, and economise excessive handling.

I was disappointed in the arrangements of many of the butter and cheese factories; for, whilst cleanliness and sanitation in almost every instance could not be improved upon, there appeared to be a general disregard for labor-saving methods from the delivery of the milk and its treatment afterwards. I was also surprised to find that margarine-making is now being developed on a much larger scale.

COW TESTING.

The most striking feature of the whole trip was the methodical manner with which each individual cow is tested, both for quantity and quality of the milk produced. In 1903 the system was first tried on 34 herds of 1,342 cows, and so satisfied were the owners of the different herds of its advantages that this year on 435 herds of 18,000 cows they have adopted testing.

It has been found by systematic testing, extending over 34 herds, that the average of the best cow was £14 10s. 10d., whilst that of the worst cow was £7 14s. 7d., both animals costing the same amount in upkeep. The Highland Agricultural Society have a staff of testers, who travel around the various dairies, and superintend the testing at different periods, and enter the records in a book kept by the owner, which is carefully inspected by the prospective buyers, and the price offered is based upon the milk records of the cow intended for sale.

ABATTOIRS.

Glasgow and Edinburgh have both recently constructed new buildings for this purpose which I was able to thoroughly inspect. However, the coolness of the climate, method of dressing, and quietness of stock make the local conditions so entirely opposed to those that apply in Australia, that a comparison is almost impossible. One feature is predominant, however, and that is the cleanliness, and the facilities in construction to aid it. The overhead trolleys and hoists are the best I have seen anywhere. Prior to the construction of the Glasgow abattoirs, a deputation of butchers, councillors, and superintendents visited the main abattoirs of the Continent to formulate ideas in construction; and consequently I noticed several continental devices embodied in the general scheme.

ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board was held on Wednesday, July 10th, there being present Messrs. A. M. Dawkins, G. R. Laffer, J. Miller, F. Coleman, G. F. Cleland, C. E. Birks, T. H. Williams (Chief Inspector of Stock), C. J. Valentine, G. Jeffrey, Professor Lowrie, Professor Perkins, and G. G. Nicholls (Secretary).

ELECTION OF OFFICERS AND WELCOME TO NEW MEMBERS.

On the motion of Mr. Laffer, seconded by Mr. Cleland, Mr. A. M. Dawkins was unanimously re-elected Chairman for the year.

The Chairman welcomed Messrs. F. Coleman and C. E. Birks, who had been appointed members of the Board by the Minister since the last meeting.

On the motion of Mr. Miller, seconded by Mr. Valentine, Mr. G. R. Laffer was unanimously elected Vice-Chairman.

SEA SHELLS FOR LIMING.

Professor Lowrie produced for inspection samples of sea shells obtained from the spit at Kingscote, which had been recommended for use in liming soils. Mr. Birks said that there was a deposit of similar shells, ranging from 100yds. to half a mile wide, and from 5ft. to 20ft. deep, extending from Port Broughton almost to Port Pirie. The shells were in layers, and could be handled without difficulty. He was wondering whether it would be possible to convert the shells into quicklime by burning. If so, there was an abundance of wood available for the purpose. Mr. Laffer mentioned that about 1,000 tons of shells a year were removed from the spit for use in the pottery works, and the smelters also used them. Mr. Birks added that the smelters had taken large quantities of shells from the deposit to which he had referred, but, owing to the introduction of a new process in smelting, had discontinued the practice. At the instance of Mr. Miller, Mr. Birks promised to obtain three samples of the shells for analysis.

VETERINARY CLASSES.

The Secretary reported that the Minister of Agriculture proposed to establish short courses of lectures on the treatment of stock in health and disease at various centres in the State. With that in view, the Director had forwarded circulars to the different branches, explaining that "before proceeding to organize a scheme, or make an appointment of a lecturer, he wishes to know how many of the Bureaux would be prepared to establish such classes. The conditions proposed were that at least 20 farmers or their sons shall be enrolled

at each centre before the services of the veterinary lecturer will be available. The arrangements for the lectures will be made by a local committee or the Agricultural Bureau. A fee may be charged by the committee to pay for hall and light, but should not exceed a few shillings. After each lecture an opportunity will be given to the farmers to ask questions pertinent to the address, and a day will be devoted at each place following each lecture for the officer to give demonstrations on such subjects as the treatment of wounds, the administration of medicine, and the diagnosis of the more common ailments. The lectures will be given on one night each week for four weeks, and the lecturer will have two places to attend and at which to lecture each week. In the northern areas the four lectures will be on the common ailments of horses, and in the dairying districts two will be on those subjects and two will deal with diseases of cattle." Members of the Board thought the idea an excellent one.

NOXIOUS WEEDS.

The Secretary reported that the recommendations made by the Board at the previous meeting in respect to the destruction of noxious weeds had been sent to the Minister of Agriculture. Cabinet had now decided that the matter could not be settled until the subject was recommended by the local governing bodies. Mr. Laffer said that this would mean, evidently, that things would go on in the present slipshod manner for all time. Mr. Coleman said it seemed that the matter should be referred to the District Councils Association, which, he considered, had not manifested the keen concern in the subject that it might have done. Mr. Laffer pointed out that the recommendations were the outcome of a resolution agreed to at the Farmers' Congress, and had been invited by the Minister of Agriculture. "Now," he continued, "they say nothing can be done without an expression of opinion from the district councils." Mr. Jeffrey suggested that as the Government did not seem inclined to take any action there was nothing more for the Board to do. This view was indorsed by the other members, and the next business was called on.

FARM LABORERS' BLOCKS.

Referring to the proposal that the Government, when opening up new lands, should set apart small areas for homesteads for farm laborers, the Secretary intimated that the recommendation on the subject had been brought under the notice of the Minister of Agriculture, who had replied that the scheme outlined was not practicable, and as only 33 out of 132 Branches of the Bureau had voted in favor of it, he could not advise the Government to adopt it.

FEW REPLIES FROM BRANCHES.

Mr. Birks desired to learn why more of the Branches did not reply to the definite questions sent from time to time by the Secretary of the Board,

It seemed remarkably strange, for example, that out of 132 Branches, only 45 had properly acknowledged a question to which an answer had been sought by Mr. Nicholls. Surely some means could be adopted which would cause the Branches to respond. Mr. Laffer suggested that the subject should be brought forward at the Congress in September. Mr. Nicholls said he intended to address the Congress on the organization and work of the Branches, and would refer to the point raised. He believed if he had persevered he could have obtained replies from all Branches in the case indicated by Mr. Birks; at the same time it had to be borne in mind that some of them were not interested in the subject, and, therefore, no doubt, had not felt called upon to express the wished-for opinion. There had been a distinct advance in the efficiency of the Branches lately, and he trusted to witness still greater improvement in the near future.

WOOL FOR AMERICA.

Mr. Jeffrey directed attention to the fact that this year there probably would be a marked shortage in the supplies of sound wools in the Commonwealth—particularly in those parts whence the bulk invariably was drawn—suitable for American competition. He therefore urged the growers in the localities in South Australia where the wools were of the right sort, to exercise special care in the preparation of their clips, as signs were not wanting that the American buyers would be here, and would be ready to pay good prices for good wools well got up.

EGYPTIAN CLOVER.

Professor Perkins asked that the Secretary should ascertain what results had been recorded by those who had received samples of Egyptian clover (Berseem) seed from the Government. The season had been altogether against the fodder, and he was the more curious, therefore, to know what success had attended the efforts of those who had grown it. The yields at Roseworthy College were not proving so heavy as in 1911. The first cut had averaged between 5 tons and 6 tons to the acre; but the second, which was practically ready, would, he believed, be better. Without the clover he did not know how they would have managed to keep the dairy going.

WHEAT EXHIBITS AND PRUNING AND SPRAYING.

Mr. Coleman brought under the notice of members the fact that the Royal Agricultural Society was considering the question of increasing the wheat exhibits at the March Show, and was striving to arouse interest among the Branches of the Agricultural Bureau, with a view to secure new exhibitors and induce the older exhibitors to show in more classes. Mr. Laffer said the Horticultural Committee of the Society was making arrangements for a vine-pruning competition and tree-spraying demonstration shortly, which should be of great interest to vinegrowers and orchardists.

ARTESIAN WATERS.

The Chairman mentioned that recently he had been reading Professor Gregory's interesting book on "The Dead Heart of Australia," in which the opinion was advanced that the artesian water supplies were not inexhaustible, and that consequently much valuable water was being allowed to run to waste. Personally, he (the Chairman) would like the Government to have inquiries made on the subject, and the correctness or otherwise of Professor Gregory's view definitely determined.

ARSENATE OF LEAD.

A request was received from the Lyndoch Branch that the Board should endeavor to secure a certain line of cheap arsenate of lead, for which it was said the Victorian Government had received an offer from England. It was decided to inform the Branch that the South Australian Fruitgrowers' Association had the matter of arsenate of lead supply under consideration.

NEW BRANCHES.

The formation of Branches was approved as follows:—

Fredrichsvalde.—Members—Messrs. A. G. Reichelt, F. W. Duldig, P. Goodfellow, T. Pfitzner, F. Pfitzner, E. A. Reichelt, F. Heintze, J. Heintze, F. W. Schutz, E. Duldig, W. Beisel, J. B. Coombe.

Berri.—Members—Messrs. A. R. Hahling, R. R. Kookay, A. Simon, T. Simon, R. W. McCreanor, B. A. Arndt, F. R. Arndt, A. P. Wishart, J. McGilton, W. Powell, W. H. Wade, T. J. McCreanor, S. E. Edwards, A. Jarvis, W. R. Lewis, H. Wescombe, S. Phillips, H. R. Antuar.

MEMBERSHIP.

The following gentlemen were admitted as members of the undermentioned Branches:—Hooper—J. R. Beck; Maitland—A. Jarrett, R. Bagshaw, A. Darling, H. W. Tossell; Coorabie—C. Fox, V. Kingsley, R. Weston; Monarto South—J. Hartmann, E. Hartmann, J. G. H. Paech, J. Frahn, B. Hoff; Carrieton—T. H. Fuller, J. W. Hardy; Penola—F. R. Field, W. Hoffman, V. L. Lampe; Butler—J. C. Humphrys; Millicent—W. Downs; Shannon—W. Watkins, W. Wemyss, C. Wemyss; Paskeville—E. G. Lamming; Coomooroo—H. Fisher, jun.; Parrakie—R. F. Jose, R. L. Beddome; Geranium—F. T. Threadgold; Pine Forest—W. A. Attenborough; Kanmantoo—W. G. Johncock; Parilla Well—B. Jackel, P. Jackel, L. Jackel, G. Pahl, B. Pahl, J. Pahl, J. Flavel, sen.; Belalie North—J. Hodby; Pinnaroo—W. H. Chapple, J. Scales, W. Pickering; Northfield—J. Dall; Willowie—A. B. Wilkins; Port Germein—W. Teasdale, W. J. McDougall; Lyndoch—E. Filsell; Monarto South—P. B. Frahn, F. A. R. Peach, G. H. Paech, G. H. Gogol, J. A. B. Schenschler; Mitchell—A. Ashman; Narrung—E. Neville, J. W. Neville; Greenock—T. Listner, L. Tummel, S. Foebiger; Wilkawatt—P. J. Rigney.

THE WHEAT MARKET.

The inactive condition of the wheat market in London during the greater part of last month was immediately reflected locally, prices for farmer's lots falling from 1d. to 2d. per bushel. At the close of the month, however, in Great Britain more disposition to trade was shown, and the market here firmed accordingly.

Dealing with the outlook for the future, *Broomhall's Corn Trade News* of June 25th states:—"Shipments last week were on a smaller scale, and for the remainder of the season will probably not prove excessive, and, as the demand for dry foreign wheat should, under ordinary circumstances, be heavy for the next two or three months, the stocks afloat and in merchants' hands ashore should tend to decrease materially and probably somewhat rapidly. The immediate future of prices will depend very much on crop and weather news. In Western and Southern Europe the outlook is fair, but certainly below last year's, even allowing for some increase in the French yield. The crops of exporting countries of Europe are shaping fairly well at present, but until the Russian spring wheat crop is assured, there can be no certainty of a good out-turn; the spring wheat crops of the U.S.A. and Canada are also more or less uncertain.

The following statement shows the actual monthly shipments from the principal exporting countries during the first three months of the new season for the years named:—

MONTHLY SHIPMENTS IN YEARS NAMED.

During First Quarter of Cereal Year.

	1910.			
U.S.A.	602,000	810,000	924,000	2,336,000
Canada	208,000	391,000	1,090,000	1,689,000
Russia	2,021,000	2,970,000	3,770,000	8,761,000
Balkans	1,482,000	2,042,000	1,833,000	5,357,000
India	672,000	384,000	472,000	1,528,000
Australia	312,000	497,000	460,000	2,269,000
Argentina	700,000	505,000	572,000	1,777,000
Sundry Countries	96,000	191,000	168,000	455,000
Total	6,093,000	7,790,000	9,289,000	23,172,000
	1911.			
U.S.A.	1,217,000	1,318,000	1,100,000	3,635,000
Canada	755,000	536,000	826,000	2,117,000
Russia	1,078,000	802,000	1,029,000	2,909,000
Balkans	698,000	1,606,000	1,297,000	3,601,000
India	461,000	347,000	327,000	1,135,000
Australia	528,000	410,000	606,000	1,542,000
Argentina	593,000	440,000	437,000	1,470,000
Sundry Countries.....	114,000	130,000	150,000	394,000
Total	5,442,000	5,589,000	5,772,000	16,803,000

The above figures may prove to be suggestive to our readers in any attempt they may feel disposed to make to arrive at an approximate idea of where the supplies are to come from during the first three months of the ensuing season. It will be noticed how important a part Russia and the Balkans usually play in providing the importing countries with their breadstuffs during the early months of the season."

STEAMER FREIGHTS.—(August 2nd)—Steamers from South Australia to United Kingdom—Continent, full cargo rates 28s. 9d. per ton (9½d. per bush.). Parcels, Port Adelaide to London—Liverpool or Continent, 21s. 6d. per ton (6½d. per bush.); Port Adelaide to Melbourne, 8s. per ton (2½d. per bush.); to Sydney, 10s. 6d. per ton (3½d. per bush.).

SAILER FREIGHTS.—From South Australia to United Kingdom—Continent, 27s. 6d. per ton (8½d. per bush.) nominal; to South Africa, 23s. 9d. per ton (7½d. per bush.).

DAIRY AND FARM PRODUCE MARKETS.

The General Manager of the Produce Export Department reports on August 3rd—

BUTTER.

The returns of cream towards the end of last month were very satisfactory, both as regards quality and quantity. The prices at the present are :—Superfine, 1s. 6½d. ; pure creamery, 1s. 5½d. With the present prospects, however, there is no doubt a reduction in price will shortly occur.

A. W. Sandford & Co., Limited, report on August 1st—

BUTTER.—The favorable rains experienced in the early part of July had a very beneficial effect on all the agricultural areas. The result has been that increased quantities of cream and butter have come along, but as the demand has been very active, satisfactory rates have been secured. Best factory and creamery butter, fresh in prints, sold at from 1s. 5d. to 1s. 6½d. per lb. ; choice separators and dairies, 1s. 3d. to 1s. 4d. ; store and collectors, 1s. 0½d. to 1s. 1½d.

EGGS.—Values throughout the month ruled very high, constituting a record. Sales have been made as high as 1s. 5½d., but at the close of the month prices came back to 1s. 3d.

CHEESE.—Very substantial business has been experienced, with rates showing a slight easing. Quotations—New make, 9d. to 9½d. per lb. ; matured, up to 10½d.

BACON AND HAMS.—July is usually a slow month for this line, but owing to the high prices ruling for the live hog, values at the end of the month showed a firming. Best factory cured sides brought 8d. to 8½d. per lb. ; hams, 7½d. to 8½d.

HONEY.—Quality lots are very scarce, it now being late in the season. Prime clear extracted, 3½d. to 3½d. per lb. ; second grades, 2d. to 2½d. ; beeswax very saleable at 1s. 2d.

ALMONDS.—Values for shell almonds have come back somewhat during the month owing to lower figures ruling in the other States, but kernels continue in brisk demand. Brandis, 5½d. ; mixed soft shells, 5d. ; kernels wanted at 1s. 2½d.

LIVE POULTRY.—The penning throughout July has been very extensive, but as demand for both local and export trade was active, rates have been very satisfactory. Good table roosters realised 3s. to 3s. 6d. each ; plump cockerels, 2s. 3d. to 2s. 9d. ; hens and light cockerels, 1s. 10d. to 2s. 2d. ; ducks (scarce), 2s. 6d. to 3s. 6d. ; geese, 4s. to 5s. ; pigeons, 7d. ; turkeys, 7½d. to 10d. per lb. live weight for medium to good table sorts.

CARCASS MEAT.—Demand has been very good, and all quality lots met with keen competition, nice rates ruling. Bright handy size shop porkers brought 6½d. to 7d. per lb. ; good baconers, 5d. to 6d. ; heavy and poor stuff, 2d. to 3d. Nice dairy veal, 3½d. to 4½d. ; medium to fair quality, 2d. to 2½d.

POTATOES AND ONIONS.—Values in potatoes firmed considerably during the month in sympathy with the shortage elsewhere, while in onions prices have also improved somewhat. Quotations—Potatoes, £7 5s. to £7 15s. per ton on trucks, Gambier ; onions, £14 to £15 per ton on trucks, Gambier.

RAINFALL TABLE.

The following table shows the rainfall for July, 1912, at the undermentioned stations, also the average total rainfall for the first seven months in the year, and the total for the seven months of 1912 and 1911 respectively :—

* No report received during the month of July.

† Only formal business transacted at the last meeting.

ANNUAL MEETINGS OF BRANCHES.

The majority of the Branches will now be holding their annual meetings and electing their officers. In such cases, unless some paper is read or discussion entered upon, the reports will necessarily be classed as formal.—[Ed.]

THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the department for fuller particulars concerning the work of this institution.

REPORTS OF BUREAU MEETINGS.

Edited by GEORGE G. NICHOLLS, Secretary Advisory Board of Agriculture.

UPPER-NORTH DISTRICT.

(PETERSBURG AND NORTHWARD.)

Amyton, June 25.

(Average annual rainfall, 11½ in.)

PRESENT.—Messrs. T. O'Donoghue (chair), H. R. Gum, T. Ward, M. and D. Corcoran, A. Crisp (Hon. Sec.), and two visitors.

IMPROVEMENT OF BUREAU MEETINGS.—The Chairman, in a paper on this subject, said every member should be regular in his attendance at meetings, and should recognise his responsibility to contribute something towards the programme. There was a prevalent idea that because a person's education had been to some extent neglected, an attempt by him to write a paper might lead to ridicule. This was a mistake, as what was wanted in the papers was sound knowledge based on practical experience. When a subject was brought forward for discussion, members could each give their opinion on it. Home-stead meetings were to be encouraged, as members would be in a position to see the methods adopted by others in working their holdings. Members generally expressed themselves as being in accord with the views of the writer of the paper.

Davenport, July 18.

(Average annual rainfall, 9 in.)

PRESENT.—Messrs. Roberts (chair), Messenger, Holdsworth, Bier, and Lecky (Hon. Sec.).

EVAPORATION OF SOIL MOISTURE.—The following paper on this subject was contributed by Mr. E. H. R. Messenger :—“There is no doubting the fact that evaporation is one of the most important natural forces, and the question demands the fullest attention and consideration. The controlling or arresting of a portion of this evaporation is absolutely necessary to successful gardening. The surface of the earth is largely composed of what are called capillary tubes, which are continually gasping for moisture in a dry climate. After each rain or watering these tubes have been supplied, and it is then the gardener's duty to do all he can to arrest evaporation. As soon as the surface becomes dry enough he should get to work with the plough, fork, or hoe and thoroughly break and work the ground, thereby producing a tilth or mulch which will prevent the moisture returning too rapidly to the surface and disappearing in vapor. If mulching is continued after each rain or watering much moisture which would be beneficial to all plant life would be conserved. Should the tubes not be broken and destroyed as I have indicated, the moisture previously stored in the subsoil will soon evaporate and the earth will become dry and parched very quickly; but if, on the other hand, the surface is kept loose, we shall find the plants do much better with less water. Good cultivation is one of the most important points connected with successful gardening. Not only does the want of tilth prevent the plants from growing and sending out their root fibres in search of food, but the want of aeration prevents the growth of microbes whose business it is to cause the manure to

decompose and assume forms and combinations suitable to all plant life. In addition to the cultivation it is necessary that the soil be charged with humus. In a dry district like the north this is of the utmost importance. Humus consists of decayed vegetable matter, which should be first spread over the land and then turned in. Land without humus is dead, and although it may be rich in all the other elements of plant food, without humus the crop will be of little value. In experiments conducted at Minnesota it was found that continuous cropping for eight years caused an annual loss of over 2,000lbs. of humus per acre, due to the fermentation and decomposition of organic matter in the soil, causing it to be less retentive of moisture, lighter in color, and heavier per cubic foot. It is absolutely necessary that humus should be provided to form a home for the bacteria upon which it is now known depends largely the conversion of the soil elements into available plant food. It is also necessary to keep the soil open, so that the sun and light may penetrate it, thus giving life and vigor to the plant. Humus, then, being so valuable in restoring and maintaining the fertility of the land, it is of the utmost importance that the gardener should know how to secure it. Some grow a green cover and turn it under, which, no doubt, is a good thing for a large piece of land, but for a small garden (fruit or vegetable) I would recommend a dressing of stable manure, because this is much quicker than waiting for the green cover to grow. I find it a good plan to cover the surface with stable manure, give it a good watering, and turn it over a few times before planting anything. Before transplanting cabbages and cauliflowers I make a trench about 4in. or 5in. deep, with a liberal amount of manure well worked into the soil, and put the plants well down, say 18in. apart, and keep them well watered and cultivated. In fact, my method is to water and cultivate alternately for a few weeks, and as the plants grow, fill in the trench, which is of great advantage and assistance to the growth."

Hawker, July 2

(Average annual rainfall, 11½in.)

PRESENT.—Messrs. G. H. Wright (chair), J. Palin, B. Mansons, J. Schnell, G. Moller, J. Smith (Hon. Sec.).

STONE-GATHERING.—A short paper on this subject was contributed by Mr. J. Palin, in which he stated that the farmers should get stones off their land before the crop attained any height. It was a very tiresome occupation to do this by hand, and every encouragement should be given to implement manufacturers to devise a machine that would either lift the stones into drays or put them into rows.

Mount Remarkable, June 26.

(Average annual rainfall, 21in.)

PRESENT.—Messrs. L. A. Bauer (chair), W. Foot, M. G. Giles, N. S. Giles, J. McIntosh, H. H. Davie (Hon. Sec.).

INFERTILE EGGS.—Mr. N. S. Giles, who had been conducting experiments with the idea of ascertaining the length of time that eggs could be kept, produced some infertile eggs that had been in store for six months. These had not been treated in any way, but were found to be in first class condition when broken.

Quorn, June 29.

(Average annual rainfall, 13½in.)

PRESENT.—Messrs. R. Thompson (chair), Cook, Schulz, Noll, Brewster, Britza, Patten (Hon. Sec.).

EXHIBITS.—Mr. Cook tabled some fine cabbages and lettuce, which were grown by him at Quorn, and much admired by members. Mr. Britza produced some very nice turnips, cabbages, lettuce, and three fine stools of Baker's Early, Newmans, and Federation wheats. Mr. Britza was of the opinion that the two former varieties were better than Federation for the Northern districts.

GARDENING.—In a short paper on this subject Mr. Britza said that the cultivation of a garden in the North was somewhat difficult, on account of the limited rainfall. He had a small garden irrigated through a pipe down the centre, to which T pieces were fixed at intervals of 35ft. The watering was done with sprinklers. He found that stable manure

was most suitable for gardening, and he made a practice of ploughing to a depth of 10in., after which the soil was worked thoroughly. For planting turnips he would mix 1oz. of seed with a gallon of sand and broadcast this.

MARES IN SEASON.—Mr. Schulz contributed the following paper:—"The mare may be served just as she is coming into season, but better just after her greatest passion of heat has passed. The best time for service is early in the morning. After she has been served let her remain quiet, or, if she seems fretful, walk her slowly about and, after 15 minutes, turn her into a pasture that she may amuse herself eating grass, but not in a pasture where there are other stock. A mare will usually receive the horse on the eighth or ninth day after foaling, even though she exhibits no particular sign of heat; if not, she may come into heat when the foal is about four weeks old. After being served, try her with the horse on the ninth day; if she refuses, try her again on the seventh day following. Upon a second refusal, try her again on the fifth day after that. If she then refuses, she may be fairly considered to be with foal. Above all things the mare should be kept away from teasing horses, from badly castrated geldings, or horses imperfectly gelded and bearing one testicle in the body; from yearling colts, and from other mares in heat. When once the time of heat is known, and service given, the mare should be returned to the horse as recommended, so that the time when the mare should receive the horse may not run over. Forty-four weeks being the usual time the mare goes with foal, if the service of the stallion is delayed it will bring the birth of the next foal too late, perhaps, in the next year, and possibly one year may have to be omitted in breeding."

Willowie, June 25.

PRESENT.—Messrs. T. Hawke (chair), E. S. Bristow, L. Hughes, E. J. Kentish, S. C. Greig, F. Richter, A. R. Wilkin, B. Bull, L. McCallum, W. P. Foulis (Hon. Sec.) and three visitors.

FEEDING FARM STOCK.—In opening a discussion on this subject, Mr. Hawke said he preferred feeding horses on long hay rather than on hay chaff. The hay should be of medium growth, not too green, and should contain a fair percentage of corn. He would not keep a horse after it had reached the age of 10 or 12 years. Mr. Bristow thought good long hay was suitable for feeding horses, but hay grown on flooded land or in water courses, as was the case with most of the hay produced in this district, was too coarse and required to be chaffed. Mr. L. McCallum thought horses should be fed on chaff in cold weather. In damp weather the hay was too tough and hard for the horses to chew, and there was a considerable amount of waste on account of it being pulled out of the mangers. There was a tendency for the horses to eat only the heads when the sheaves were long. When they were doing hard work they required grain with their feed, and this could only be given when the hay was chaffed. When chaff was dear, farmers could feed horses that were not working on equal parts of wheat and hay chaff. He would give each horse a sheaf of long hay at night, and he always made a practise of damping the chaff when mixing crushed grain with it. For feeding cows he would give pollard or bran mixed with the chaff, and molasses was also good. Good results could not be secured by feeding them on long hay. It was not advisable to sell horses when they were 10 years old, as they were then at their best for heavy work. Mr. Kentish thought horses would do well on long hay in the summer, but not in the winter. Some purgative should be added when chaff was fed to horses. Bran would have the desired effect. He did not favor selling horses at 10 years of age, but would prefer to sell the younger animals. He had secured good results from cows when fed on long hay. Mr. S. Greig said whole or crushed wheat was suitable for mixing with chaff. He had fed horses heavily on this without ill effect, except that there was a tendency for it to make the shoulders soft. Mr. L. Hughes had had better results from cows fed on dry cocky chaff than from those fed on long hay. The general opinion of members was that wheat was better than oats for mixing with chaff. A good ration consisted of chaff with a small amount of grain and a liberal addition of bran.

Wilmington, June 26.

(Average annual rainfall, 17½in.)

PRESENT.—Messrs. J. Hannagan (chair), S. and D. George, A. R. and E. J. Gloede, Litchfield, McGhee, J. and G. Schuppan, Slec, Zimmermann, B. Jericho (Hon. Sec.), and two visitors.

AGRICULTURE IN THE EARLY DAYS.—Mr. Payne read the following paper :—

"It will not be an easy matter to say in a short paper all that is forced upon one's memory respecting the vast developments that have taken place in our agricultural industry during the past 50 years ; but it may be possible to touch on points which have proved such great factors in the up-building of agriculture in this State. My first recollection of wheat-growing in South Australia takes me back to 1857, when for a time I was a resident in the Angaston District. At that time the areas cultivated were small ; a paddock of from 80 to 100 acres would have been considered extensive cultivation. The land upon which the wheat was grown had been heavily timbered, and the trees—mostly gigantic gums—had been grubbed one at a time, and the timber burnt generally, but in some few cases the large timber was converted into charcoal where there was a demand for that fuel locally. Of course, the clearing of such lands was a very slow process, and also expensive in some cases, but the labor employed in most instances was that of the pioneer himself, with such help as could be obtained from wife and children. In many instances have I seen the noble helpmeet to the honest and hard-toiling husband assisting to cut up the fallen tree with the crosscut saw, and help roll the logs into a heap to be burnt. Boys and girls alike toiled hard, early and late, to aid their noble father in his praiseworthy efforts to increase his acreage for cultivation. It will be readily seen how slow the process of cultivation was in the heavily timbered districts of Angaston, Tanunda, Lyndoch Valley, Nuriootpa, Eden Valley, Mount Pleasant, Gumeracha, and many other districts ; in fact many a man has spent the prime of manhood in clearing a small holding of 80 acres—the original sections. Having cleared a small area of land, every effort was then made to break up the virgin soil, and here again the difficulties to be met with were legion. Horses were few, and most expensive to obtain, thus only being within the purchasing powers of those with capital at command, and these were comparatively few in number. The draught animals mostly used were bullocks, and these, though strong and cheaply fed and purchased, were slow in their movements, and required an extra hand to drive them ; the driver generally being a youth or strong maiden. The plough was single-furrowed, consequently the area covered in a day—though this was counted from daylight to dark, virtually—was very small, and the more so when in contrast with the machinery of to-day. Ploughing completed, the work of broadcasting the seed was begun. It was all done by hand ; and then followed the harrowing, which was done in many instances by a young woman, whilst her father was busy sowing. The land being rich and the rainfall liberal, the growth of the wheat was rapid and healthy ; and 40bush. per acre was considered a fair crop. Often have I seen paddocks which gave 50bush. and over. The crop ripened, now came another task—that of gathering the grain. No strippers or harvesters were available then. All had to be cut with the sickle, and afterwards threshed, either by the travelling steam thresher, or trampled out by bullocks or horses ; but in most cases it was done with a grooved roller. The cleaning of the grain—excepting again with the better financed man—was of a most primitive character, consequently slow, and demanding all the hands available. The grain secured, then followed the carting to market, and this involved long travelling and camping out, and was mostly done with bullock teams. The prices obtained varied from 6s. to 8s., and sometimes went up to 12s. and 13s. Still, for many years the income gained was scanty, but being in most cases wisely and economically husbanded, in course of time accumulated, and placed the head of the family in more comfortable circumstances, and provided capital for further land purchases. It was a battle in which all who could work were called upon to do their utmost, and I believe I am justified in saying that the help was given cheerfully. By-products were not lost sight of—cows and poultry were requisitioned to add to the income. In small towns the demand for butter and eggs was very limited, and so a better market had to be sought, at the expense of a weary tramp over long miles. Often have I seen a strong young woman of from 18 to 20 years travel from Angaston to Gawler and back again the same day, a distance of 22 miles, carrying a box of butter and eggs slung over her shoulder, and bringing back necessary groceries purchased by the produce sold. This was done for some years by many, until improved circumstances permitted the purchase of a horse and spring cart. It is not necessary that I should elaborate upon such episodes of the life of the agricultural pioneers of 50 years ago ; suffice it to say that the privations endured were consonant with a dogged determination to succeed, and be it said that the agricultural industries of to-day have been built upon the solid foundation laid by these early pioneers. In the early sixties lands in the northern areas were talked over, and soon bands of yeomanry were found ready and anxious to go farther afield where cheaper land could be obtained, and operations carried on under easier conditions. Then, in the seventies, followed the opening up of the northern areas, and this was the commencement of extensive cultivation, and the establishment of this great industry

upon broad lines. Rightly it has been stated that our two staple products are wheat and wool, and well does it behove us to see to it that the very best is obtained. There can be offered to-day no excuses for apathy or carelessness in agricultural efforts. There are so many channels through which all practical information can be obtained, that no earnest seeker after knowledge should be delayed in his movements through lack of information. Our agricultural bureaux, our scientific centres, colleges, and other authorities are so replete with the soundest and most practical training and teaching that ordinary and even special troubles may be easily removed. I cannot emphasize too strongly the intense value of the Bureau Branches. As a medium through which the most practical and soundest information can readily be obtained they are without comparison, and are worthy of the fullest support every member can give. Until within a year ago I had been a member of this Branch for 11 continuous years, and no happier or more profitable period of my life had been spent than in forwarding its interests. I would commend to every earnest townsman, and especially those in rural districts, the immense value of these branches as channels through which the very best information can at all times be obtained upon all matters of agricultural importance. I would say, as parting words—Be earnest; be thorough. Do your share of work, and do it well, and thus as time passes, we shall be helping to build up one of the finest institutions our land possesses."

Wirrabara, June 29.

(Average annual rainfall, 30in.)

PRESENT.—Messrs. P. J. Curnow (chair), J., G., and E. Hollett, J. F. Pitman, C. H. Curnow, S. Thistleton, C. F. H. Borgas, W. H. and E. J. Stevens, V. and H. Lawson, R. L. Watson, F. T. Jettner, W. Bowman, A. R. Woodlands (Hon. Sec.), and one visitor.

UNDERGROUND TANKS.—In a paper on this subject Mr. J. F. Pitman said that the concrete method of building underground tanks had proved to be superior to the mason-work system. The concrete made a much more solid wall, and was not so liable to crack. However much care was taken with the masonwork, it was impossible to build a wall without a hollow in the back somewhere. When the weight of the water was brought to bear on this it would be found that the masonwork gave way, causing a crack in the wall, and allowing the tank to leak. Where the nature of the ground permitted the digging of a ring for concrete walls, he advocated the following method of procedure:—Mark out the size of the tank and then mark another ring 16in. out, this being provision for the thickness of the wall. With the pick and shovel dig out the trench to the required depth. This could then be filled with concrete, and the earth in the centre could be removed when the concrete was set. For the concrete good clean gravel, not too coarse, should be used. If this were not obtainable, clean sand with cracked up metal would suit the purpose. One part of lime to two parts of gravel should be mixed as thinly as possible. Where it was impossible to dig out a circular trench, as before described, and it was necessary to construct the walls of stone and mortar, he thought the best means would be to build a wall with a good face and fill up the back with concrete, which should be thin enough to run into the crevices in the stones. Good, clean clay rammed in behind the wall would go a considerable way towards making it watertight; but it was essential that the ramming should be well done. It was better to make all underground tanks long and narrow, as there was then less pressure on the sides; 15ft. was a fair depth. A good discussion followed the reading of the paper. Mr. V. Lawson said underground tanks should be built wider at the bottom than at the top, for when the winter rains swelled the ground the pressure on the wall of the tank would be in a downward direction, and no amount of pressure in this way would cause the walls to crack.

MIDDLE-NORTH DISTRICT.

(PETERSBURG TO FARRELL'S FLAT.)

Burra, June 28.

PRESENT.—Messrs. F. G. Scholtz, A. E. McWaters, H. H. Thomas, J. H. Rogers, F. Duldig, H. Bagg, H. Finch, F. J. Carey (Hon. Sec.), and one visitor.

FOLLOWING.—In a paper on this subject, Mr. F. G. Scholtz said following should be started as early as possible in June, and wherever it was practicable should be completed

by August. The plough used should not cut a furrow larger than 7½ in., and the shares should be set level. A five-furrow plough, cutting a 7½ in. furrow, would be found to draw lighter than a four-furrow implement cutting a 9 in. furrow. Where the average rainfall was 14 in. or over, he would plough to a depth of at least 5 in., but 3 in. was quite sufficient where the annual fall was under 12 in. New land absorbed moisture more readily than land that had been worked for a number of years. In spite of the contention that it was inadvisable to plough deeply where a clay subsoil was near the surface, he had turned up from 1½ in. to 2 in. of clay in red sandy loam, and the crop on this was the best he secured. However, he would not advise anyone to turn up the clay in a hard, red, poor soil, as there would be a tendency for it to cake on top. He made a practice of harrowing the fallow immediately after ploughing. If the ground were fairly loose, it was only necessary to go over it once, but if it had been ploughed up wet, and set hard, it was advisable to put the harrows over it twice and then cultivate it in September, and again about the middle of October. He estimated that land cultivated in this way would return one-quarter of a ton more to the acre than land only cultivated once. The cultivator should not cut more than 6 in. between the tines. It would then destroy the weeds more effectively, draw lighter, and go into the ground better than an implement with too much dip. One team of eight good horses would be found sufficient to plough, harrow, and cultivate twice an area of 200 acres. It was a good idea, in the event of a precipitation of ½ in. or over between October and February, to put the harrows over the fallow again.

Crystal Brook, June 29.

(Average annual rainfall, 15 in.)

PRESENT.—Messrs. H. Billinghamurst, B.A. (chair), R. Shaw, B. Flavel, E. Robinson, G. Miell, R. Heaslip, W. J. Venning, G. Sargent, Jno. Pridham, I. Teakle, W. W. Lovelock, M. P. Pavy, W. S. Carmichael, G. Davidson, Jas. Forgan, W. C. Wood, B. Weston, A. E. Cooke, W. W. Robinson, and M. Weston (Hon. Sec.), and three visitors.

HARVESTING AND MARKETING WHEAT.—Mr. R. Heaslip read a paper on this subject, in which he stated that farmers would save a considerable amount if they co-operated and purchased their cornsacks direct. Continuing, the paper said—"With reference to the gathering of the crop, I must ask my hearers to remember that I am dealing with the durability of the machinery used and the cost of repairs over a number of years. I will divide the crops to be dealt with into two classes, viz., those growing on smooth or plain land, and those on hilly, rough, stony, or mullenized land. With the smooth, level country the harvester, with the present state of the labor market, is the more economical machine. In the first place the wear and tear is not nearly as great as on rougher land. The driver can better regulate the pace, and therefore produce a more uniform sample with less waste than can be done upon hilly, stony, or stumpy land. In going up or down hills it is a difficult matter to drive the winnower at a regular speed. When ascending the rate of revolution of the fans is reduced and more of the heavier particles pass through the sieves into the corn box. In descending, unless great care is taken, a certain amount of the corn will be blown over the sieves and out with the chaff. With regard to the stripper and motor winnower I am quite conversant with the labor difficulty at harvest time, but I still think that on rough and hilly ground it is the more economical machine. It has this advantage over the harvester--the wheaten chaff, which has a fair value, especially in the drier seasons when hay is scarce, and in new mallee or stony country, where it is troublesome to work the binder, is saved. Having arrived at the best means of harvesting, the next point is the disposal of the wheat. Any farmer, say, within three or four miles of a railway station can with profit keep his wheat in his barn rather than store it with the merchants. By retaining his wheat he has a choice of buyers instead of being practically bound to take the price offered by the firm with whom it is stored, and this sometimes means several pence per bushel. I consider the practice of leaving the storage notes in the hands of agents, instructing them to sell at the first drop, is detrimental to the interests of the wheatgrower. The merchants drop the wheat 1d. or more to call in wheat so held, when in reality the market value of wheat is on the eve of a better price." In discussing the subject, Mr. Venning expressed the view that more wheaten chaff should be saved. There was as much waste of grain with the stripper as with the harvester. Mr. C. E. Birks (Advisory Board) gave his experience in harvesting crops with the aid of the binder and thresher, the use of which had been discontinued in his district owing to the high cost of labor. They had, however, reaped an advantage this season through having the straw (eight years old) available for stock. On this the young stock particularly did remarkably well; in fact, as well as on three or four year old

hay. He did not think there was much waste with harvesters if they were properly worked. Mr. Cooke referred to the fact that although farmers generally were in favor of the harvester Professor Lowrie was not an advocate of its use. Members generally agreed with the views expressed in the paper.

Georgetown, July 15.

(Average annual rainfall, 18in.)

PRESENT.—Messrs. J. Freebairn (chair), M. Hill, G. Hill, M. J. McAuley, A. Erickson, J. Wyatt, A. Thomson, S. Eyre (Hon. Sec.), and two visitors.

FALLOW.—In a paper on this subject Mr. M. Bond said that where land was clean he did not think it would make any difference whether it was ploughed deep or shallow, but the chief difficulty in this district was to get the land clean. To plough dirty land deeply was a mistake, as the weeds would not grow until the following winter, and at sowing time it would be necessary, in order to kill the weeds, to plough too deeply to provide a good seedbed. He advised burning the stubble and the hay stumps, and if this could be done early, a good proportion of the mustard and sheepweed seeds would be destroyed. It could then be cultivated before sowing time as deep as could be done without rooting up too many stumps; but it was better to only scratch it over than to make it lumpy. After sowing it should be gone over again whilst the rubbish was young. Where the ground was so wet that it required a greater strength than was available to pull through, every other tine of the cultivator could be hooked up. This would bury the weeds that were not cut. The idea which prompted the working was to secure a growth of weeds after every cultivation. Land that had been left out for a few years would be found very difficult to deal with, especially if it had been covered with mustard yearly. The most suitable means would be to burn after harvest, and then treat it in a manner similar to that advocated for stubble land. Or if it were thought that the dry grass could be covered, a light ploughing might be given with advantage. The share preferred by the writer was one 8in. long and 7in. wide for a cultivator that cut 6in. a tine.

Georgetown, July 27.

(Average annual rainfall, 18in.)

PRESENT.—Messrs. W. J. Freebairn (chair), M. A. Hill, M. J. McCulley, R. J. McDonald, A. Thompson, E. Hewitt, S. Eyre (Hon. Sec.), and one visitor.

CO-OPERATIVE SHEARING.—The paper on this subject read by Mr. J. J. Cormack, of the Amyton Branch, and printed on page 1276 of the July issue, was read and discussed. For the past three years a system of co-operative shearing had been carried out in this district, and a number of members of the Branch were shareholders. Members agreed that the idea was a good one and it had worked well in the case under notice.

Gladstone, July 1.

PRESENT.—Messrs. R. E. Lines (chair), W. Brayley, J. H. Sargent, T. Hollitt, T. J. Brown, A. J. Anderson, T. A. Sandow, A. B. Blessing, W. Growden, P. Sampson, W. T. Sargent, F. Aughey, J. S. and G. A. Fisher, P. Masters, R. G. Peters, G. M. Black, E. H. Davies, H. Fay, W. Odgers (Acting Hon. Sec.), and four visitors.

SHEEP.—Mr. W. H. Brayley read the following paper :—“It is now generally recognised amongst farmers that no farm is complete without a flock of sheep, if it is only to keep the homestead in mutton. It is much cheaper to grow one's own mutton than to purchase it. Sheep well managed can be made a very profitable source of income, either in the way of wool and mutton or the raising of lambs for the export trade. In the first place care must be taken not to over-stock. It is better to err the other way. Of course, in a season like the present the most careful farmer is perhaps very short of feed, but every farmer should have some surplus hay on hand to help the stock when the season is late.

In every case the breed of sheep a farmer keeps must be determined by the question whether wool or mutton or the raising of lambs for the market is the object. In the north of this State the Merino is the best all round breed to start with. The best fat lambs are usually bred from ewes strong in Merino blood, but I am not sure that better results in this line of lamb-raising for the market cannot be obtained by breeding from ewes of the first cross only. They are quieter and make better mothers, besides being more prolific than the Merinos. When breeding for wool production the best Merinos that the farmer can procure should be used. By the judicious introduction of new blood every year or two, constant culling, and using good rams, he should secure good returns. Sheep, like all other stock, require plenty of feed and water, more especially the latter, when feeding on dry stubbles during the hot summer months. Under such conditions they do best when they can go to the water whenever they feel disposed. The more sheep are left to themselves and the less they are disturbed the better. Sheep that have to be driven any distance to water generally carry a very much dirtier fleece. When kept on a farm under cultivation for cereals, and made to do the work on the fallows that should be done by the cultivator, they will not produce their wool in such good condition as they are capable of doing under more favorable circumstances. Clearing the fallows and fattening lambs do not work together in the average season. Care should be taken to provide suitable feed if lambs are to be successfully marketed. When lucerne can be grown lamb-raising can be made a profitable business. When wool production is the objective, just before shearing go through the flock and cull out all the old and inferior ewes. You should have younger ewes to take their place. The culls, if not wanted for mutton on the farm, should be sold as soon as shorn, as they are generally then in good condition. If they have reared lambs, wean the lambs from them as early as possible after the ewes are shorn and before the feed becomes too dry, and they will soon be fit for the market. The shearing should be done before the seeds are likely to get into the wool. The marketing of clips from an average sized farm on the lines adopted on large stations does not pay. An average farmer would scarcely have more than one or two bales of a sort, and therefore where one has a clip of 10 bales or under the best plan is to take off the bellies, portions of the breech, and all the stained parts around the edges. By heavily skirting clips from small flocks too many parts of bales are put up, and the bags go into the "star lots." With flocks of 2,000 or over the deeper skirting may be carried out, as there is so much more material to work on. All broken fleeces should be kept out, and if there is not enough to make a bale these may be put into bags. This is not generally worth so much as good belly wool. All that is required with the clip from the small flock is to brand the bales with the sex and the class of wool, such as fleece, lambs, bellies, pieces, or locks. I believe in classing the wool to the utmost limit that can be afforded, according to the size of the flock. From past experience I am satisfied that there is a good profit to be made from keeping sheep on the farm." An interesting discussion followed the reading of the paper. In reply to a question, the writer stated that Merinos were inferior to the Shropshires for early lambs, but the best freezers were secured when these were crossed. It was advisable to introduce fresh blood into the flock at periods of three years. Sheep should not be put on fallow just prior to being shorn, as the wool became dirty. Dipping was not necessary in this district, although he had tried it and the result was an improvement.

MERINO WOOLS.—A handsome gift, in the shape of a glass case of Merino wools, was presented to the Bureau by Mr. Brayley.

Port Pirie, June 1.

(Average annual rainfall, 12½ in.)

PRESENT.—Messrs. E. B. Welch (chair), H. G. Hawkins, T. Johns, D. McEwin, A. M. Lawrie, F. A. Johns, H. F. Richter, J. Greig, T. B. Jose, and W. R. Wright (Hon. Sec.)

CO-OPERATIVE MARKETING.—Mr. H. G. Hawkins read a paper on this subject, in which he stated that the aim of the farmer should be to secure the greatest return possible from his land by adopting the most economical and up-to-date method of production, and then to dispose of his produce to the best advantage. This could be done by co-operative marketing. There were too many middlemen engaged in this business, and as these had to be paid the farmer suffered. The heavy commission, &c., which were paid on farm implements and machinery could be done away with also in this way. In discussing the subject, Mr. Grieg said co-operation was the solution of the marketing problem, with which opinion members generally concurred.

Port Pirie, July 6.

(Average annual rainfall, 12½in.)

PRESENT.—Messrs. J. Greig (chair), T. B. Jose, C. E. Birks, H. F. Richter, F. A. Johns, A. M. Lawrie, H. Brine, W. R. Wright (Hon. Sec.).

SOIL CULTIVATION.—The following paper was read by Mr. C. E. Birks:—"This, to the agriculturist, is the most important function on the farm, for success depends to a great extent on the thoroughness with which it is carried out. Not even in one district, much less one State, can any hard and fast rules be laid down to guide the operator. When the general principles underlying good cultivation are mastered the successful application of them to any particular soil is where care and experience are required. Two soils may be of somewhat similar nature, yet they may require very different treatment on account of the local conditions being different. Good cultivation does not necessarily mean frequent workings, for there is such a thing as overworking a soil; that is, getting it into such a fine state that a heavy rain makes it run together like cement, and unless worked up immediately after the rain (which is only possible on small areas) it breaks up in a more lumpy state than when first worked. Disking before the first ploughing has a lot to recommend it in a limited rainfall area. Firstly, by breaking the surface and stopping evaporation, the ploughing can be continued so much longer in the event of a dry spell; secondly, the land breaks up more crumbly than when not disked; and, thirdly, the plough deposits the finer soil in the bottom of the furrow, leaving the rougher particles on the surface to be dealt with by the subsequent workings. If the nature of the land and condition thereof as regards moisture (being not too wet) permit of harrowing immediately after the ploughing, so much the better; for this is where there is such a loss of moisture on account of the extra surface exposed to the air. If these operations have been done under favorable conditions the weeds will soon necessitate another working; and it is here that one must use discretion in the choice of the implement, according to the nature of the soil. In any case the weeds must be effectually killed, but in one soil it will be necessary to leave a fine crumbly surface, in another a rough, cloddy surface. If the latter sort of soil were worked to fine tilth on top it would run together with the first rain of any importance, a crust would form, and evaporation take place so rapidly that much of the good of fallowing would be lost. Of course, it must be worked as soon as possible, and this is where the trouble lies. Continued rains mean continued working, and that brings about the fine state of surface that we want to avoid in this soil; and yet, if a loose mulch is not kept on top the rains in the summer months are not only lost, but are the means of a loss of the stored moisture. The soils that are subject to this drawback are, as a rule, deficient in organic matter, and until that is supplied it will always be difficult to know how to conserve the maximum amount of moisture without paying too dearly for it in cultivation. Two good heavy fodder crops would go a long way to lessen the evil; but, better still would be the adoption of a system wherein fodder crops which would pay their way as well as tending to make the stiffer soils more friable and consequently more easily worked and less liable to form a crust, play an important part. In the case of the lighter soils, more frequent working can be taken advantage of, as the cost is less and there is not the same tendency to cake; again, here the above practice can be well put into force, inasmuch as it puts more body into the soil, to say nothing of increasing its fertility. Providing care has been exercised in the depths of the different cultivations, by the autumn there should be a clean field, with 2in. or 3in. of loose fine, or comparatively fine, soil overlying a good solid seed bed, made up of fine particles packed together by the continual working above it, and in perfect contact with the unworked soil and subsoil, and ensuring the supply of moisture for the succeeding crop by capillary attraction from the reservoir below. It is possible to retain in this reservoir practically all the rainfall for the year by thorough cultivation, and if the subsoil is not of too porous a nature, make use of it for the plant. Very few fallows are so well worked that no weed seeds are ready to come away with the wheat, but by choosing the correct time for drilling in the wheat (that is, only drilling when the top mulch is too dry for small seeds to start in, the wheat being deposited in moist soil) it comes away at once, and unless rain falls within three or four days it will be far enough ahead to smother the weeds, except such as oats, turnips, and star thistles, which will force their way through any crop. Harrowing the growing crop is an operation well worthy of consideration in some cases." In replying to a question in regard to the harrowing growing crops, the writer of the paper said that the most suitable time for conducting that operation was from the present time until about three weeks hence, according to weather conditions. Crops should not be harrowed before the wheat plant had sent up its second leaf. The idea of harrowing was to break the top crust of the soil to stop evaporation in order to preserve all available moisture until the plant was well rooted and strong enough to resist a dry spell in the weather.

Mr. Lawrie agreed as to the beneficial effects of harrowing, especially in regard to crops on stiff clay land. Mr. Greig said that climatic conditions greatly influenced the farmer in his operations. He believed in the principles as advocated in the paper.

Redhill, July 1.

(Average annual rainfall, 16½ in.)

PRESENT.—Messrs. F. Wheaton (chair), McAvaney, Lines, Hayes, Prevost, E. Steel, Stone, Holmes, Briggs, Pengilly, P. H. and F. A. Wheaton (Hon. Sec.), and one visitor.

SHEEP AND WOOL.—Messrs. P. Wheaton and Prevost contributed the following paper :—“That South Australia offers great advantages to the industrious man on the land cannot be denied. It is difficult to imagine a more prosperous class of farmers than those inside Goyder's line of rainfall in South Australia. There is no doubt that the carrying capacity of land since the introduction of artificial manures has been greatly increased. While on some farms, however, more sheep are kept than should be, others are found to be understocked. In the former case the result of the clip is generally disappointing. The clip from a small but well-conditioned flock realises more than a large scantily-fed one. It is all very well to keep a large flock in good years, but the bad seasons have to be reckoned with. The breeding of fat lambs for market is a source of revenue for the farmer in this district. The market in Europe is almost unlimited, and the breeder can always get a ready sale for his fat lambs. A matter of importance is the kind of ewe kept. For the purpose of fat lamb raising, no doubt the most profitable breed is the Merino, for not only do those sheep produce excellent lambs when crossed with the Dorset Horn or Shropshire, but their wool is always worth 50 per cent. more than that of any other breed. They will also live in bad years where other breeds will perish. It is a good practice for the farmer to pick out a few of his best ewes, i.e., those large framed and well covered with a good bulky wool showing a good length of staple, and mate them with a well-bred Merino ram, in order to keep up the standard of the flock. All old broken-mouthed ewes should be got rid of. Lambing ewes should be kept to themselves, and should not be unnecessarily disturbed. Whether the ewes be young or old, it is a good thing to frequently walk quietly through the lambing paddock unaccompanied by a dog, and give the assistance often required. This may save the lives of many ewes and lambs. It is most necessary, if farmers wish to get the best results from their lambs, that they should have an abundance of green feed. The ewes should be in good condition before lambing, in order that they may give the necessary sustenance to their offspring. Small paddocks are a great boon, as sheep can be frequently shifted; thus the pasture is always fresh. To get satisfactory results, one ram should be yarded with each 50 ewes for about eight or nine weeks. The dates when the rams are put in and taken out should be noted, so that one knows when the ewes have finished lambing. One hundred and fifty days is the pregnancy period of a ewe. It should be realised that the rams should not be put in too early or late. About four weeks after lambing has terminated is the usual time for earmarking and tailing all lambs and castrating ram lambs. For tailing the searing iron is preferable to the knife. The latter causes an unnecessary loss of blood, and the lambs tailed with a knife seem more susceptible to the blowfly pest. It is the general practice among farmers to shear their own sheep. Of course the blades are used mostly. Second cuts should be avoided, and it should be seen that the sheep are shorn clean. All sheep should be dagged before entering the shed. If a good price is expected for the wool, it is most necessary that it should be properly classed. Where the flock is all Merino, and is not very large, it is not advisable to make too many lots. Farmers should never class on quality, but on condition. All the fleeces which are extra greasy and heavy, as well as the yellow, discolored pieces, in addition to the belly wool, should be kept separate. All fleeces should be skirted before being rolled. With small flocks heavy skirting is unnecessary, but the sweaty and dirty edges should be picked off. If one or two burry fleeces are found in a flock, keep them apart from the balance of the wool. If a buyer sees them mixed, his estimate of the value is greatly affected. Farmers will find it bad policy to go in for breeding light, fine wool. If the flock is fairly large it pays to skirt off the breech, which should be branded as pieces. All dirty, poor, and irregular wool should be taken off. If a broken or tender fleece is found it is advisable to tear it up and put in with pieces. When the flock is large it often pays to divide the clip into several lots, but star lots should be avoided. Say, for instance, three lots are made. The first lot, which could be branded “A A” or “1st combing,” consists of the brightest, lightest, broadest-stapled, and most attractive-looking fleeces. The second lot, which would be called “A” or “2nd combing,” is a wool containing more yolk or

earth, and which is shorter and less attractive-looking than the A A's. Then a cast lot can be made, consisting of all the inferior fleeces, such as extra heavy, discolored, extra coarse, or in fact any fleeces which spoil the look of the other sorts. All crossbred wool must be kept separate. In classing Merino lambs' wool, all the shorter and heavier wool, from which the dags and stains have been taken, should be kept by itself. The long and hairy, and also burry wool, might be put with this lot. I hardly think co-operative classing would be a success, as it would lead to a good deal of dispute and dissatisfaction." Members agreed generally with the paper, which was much appreciated. The Shropshire ram was considered to be better than the Dorset Horn for the fat lamb industry. The Secretary drew attention to the fact that Southdown lambs had been tried with success at the Roseworthy Agricultural College.

Yongala Vale, July 27.

(Average annual rainfall, 13½ in.)

PRESENT.—Messrs. A. C. Fowler (chair), W. Scott, F. Laubsch, T. Battersby, W. Edson, E. Cooper, W. and T. Keatley, B. Webb, G. H. Jansen (Hon. Sec.), and six visitors.

FALLOWING.—In a paper on this subject, Mr. Hunt, a member of the Whyte-Yarcowie Branch, said that the main objects of ploughing the land was to conserve the moisture and to secure an early growth of rubbish to be cut off, in order that a clean crop should be secured. The fallowing should be done early, as soon after seeding as possible, and the farmer should use that particular kind of plough which best suited his soil. The great advantage of early fallow was that it exposed the soil to the atmosphere for a longer period, and the heavy winter rains readily penetrated to the subsoil to be conserved for future use; moreover, it was easier to obtain consolidation of the seed bed. With late spring fallowing much winter rain was lost by evaporation and surface drainage. However, heavy red clay soils, which tended to break down rapidly under the influence of winter rains and which set very hard in the dry weather, should be left until the light soil was fallowed. A modification of the Campbell system of dry farming was being carried out in this State. This system required the harvester to be followed up by a double disc, but in South Australia the surface of the soil was so hard and dry at harvest time, excepting in limestone and sandy soil, that this was not practicable. The system of cultivating land to be fallowed in February and March had been adopted in the drier areas with satisfactory results. This enabled the autumn rains to easily penetrate the subsoil and also favored the germination of rubbish, which could be destroyed when fallowing. When deciding the depth to which to plough his land the farmer should be guided mainly by the character and depth of the soil. In America it was not an uncommon thing to plough to even 12 in. in the drier parts. In South Australia the average depth was probably between 3 in. and 4 in., and rarely did a farmer exceed 5 in. Deep ploughing was undesirable where the soil was shallow, or on limestone country. No benefit was derived by bringing clay subsoil to the surface. Generally, provided the soil was of sufficient depth, it would be found that deep working was better suited to dry districts. One of the objections raised to this was the time involved and the cost of the ploughing, but the extra return from the crop should more than compensate this. At Hammond, with an average rainfall of 9 in., deep ploughing experiments were tried. The returns from the land ploughed to a depth of 6 in. were over 3 bush. to 4 bush. more per acre than the return from plots ploughed 4 in. deep. The general rule was where the soil was naturally deep it was profitable to work deeply. The writer was of the opinion that deep ploughing had been discontinued by a number of farmers in the dry districts because they were unable to secure firm and consolidated seed beds. In wet districts this was an easy matter, as the heavy rains tended to break up the soil. The best means known of obtaining a solid seed bed was the use of the harrows, which should be put over the land as soon after rain as possible. It was practically useless to harrow heavy clay soils when they were dry, especially if they were at all lumpy, as this left the land open and very little moisture was conserved. He recommended the harrowing of fallow land as finely as possible to secure the germination of all rubbish and the conservation of as much moisture as possible. An interesting discussion followed the reading of the paper.

PLOUGHING IN STUBBLE.—The advisableness of ploughing in stubble was discussed, some members favoring the idea, whilst others were opposed to it. Attention was drawn to the fact that where the stubble had been raked together and burned it was clearly to be seen in the following crop where the burning had been done, even although the ashes had been scattered about by the wind.

LOWER-NORTH DISTRICT.

(ADELAIDE TO FARRELL'S FLAT.)

Balaklava, July 13.

(Average annual rainfall, 15½ in.)

PRESENT.—Messrs. H. P. Burden (chair), T. A. Thomas, P. Roediger, O. Uphill, H. M. Tuck, J. Spillane, H. L. Twartz, G. C. Neville, B. R. Bayer (Hon. Sec.), and one visitor.

STAR THISTLE.—Attention was drawn to the prevalence of star thistles in the district, and the possibility of successfully reaping crops dirtied by this weed was discussed. Mr. Thomas had found a "chopping comb" attached to the machine very useful.

BOT FLY.—The Secretary passed around for inspection a bottle containing a small portion of a horse's stomach and a quantity of bot fly chrysalides. The specimens had been removed from the stomach of a horse by Professor Higham several months ago. He read an extract from a veterinary work showing the remarkable vitality of the bot chrysalis, which lived for hours in oil of vitriol, corrosive sublimate, and other powerful chemicals. It was impossible, therefore, to give the horse anything that would destroy the chrysalis without injuring the stomach. Mr. Neville said if the hair were clipped from under the horse's chin and some of Professor Higham's mixture applied, that was sufficient to keep the fly away from the horse. Some of his horses are attacked every year, and others escaped. A man he had working for him used to tie a piece of red cloth under the horses' chin to keep the fly away. Mr. Spillane thought the keeping of the fly away from the horses was the best remedy. This could be done with working horses, but not with young stock running about, and these latter spread the bot fly. He had used carbolic salve with good effect. The Chairman said it was dangerous to go out with a harvester with some horses when the bot fly was about. He had always used Professor Higham's ointment and found it effective when put under the horses' chin.

Blyth, July 29.

PRESENT.—Messrs. A. L. McEwin (chair), Dunstone, Zweck, Ninnes, Roberts, W. Pratt, A. A. Schulze, M. S. Longmire, Clarke, Buzacott, Lehmann, Schuster, Podler, H. W. and W. O. Elme (Hon. Sec.), and one visitor.

LIMESTONE.—Mr. R. Buzacott, in a lengthy paper, stated that generally speaking the limestone on the scrub land in this district was hard, which made it more valuable, both for lime and road-making purposes. With the stones left as they were they constituted a hindrance to cultivation. If, however, it paid to crop the land with the stones on it, surely the work of clearing would be compensated by a handsome return. In addition to this there should be a direct return from the stones themselves. Continuing, the paper said—"I believe we have in these stones a valuable asset. There are no better stones in the State for lime-burning. The cost of burning would not be so great where the wood is on the spot. When Mr. A. L. McEwin had the Mallee Brao kilns in full swing the lime from there was very popular, and I have heard it said again and again that there was no better lime in the State than that burned at the Mallee Brao kilns. Another use for the stones in their raw state is road making. Our roads generally are not too good, and there should be a demand for good hard limestone, and you who are fortunate enough to have the limestone on your land should find it a source of revenue. The district council should be at all times buyers of stone suitable for road-making, so that the farmer coming into the town for his superphosphate or produce of any kind need not come in with an empty wagon, but every time bring in a load of stone. About the time when the phosphate is due to arrive at the railway station bring the team in with a load of stone to the council. This will save demurrage on your phosphate, save the expense of paying a man to unload, and save yourself the laborious work of loading from the ground. You will profit by so doing; so will the district council. I would suggest that the district council buy these stones by weight over the weighbridge at an upset price, saving time of measuring and of checking the several heaps delivered by the various farmers and carters at different times. When the council held their monthly meetings cartnotes could be presented and payment made. These stones could be placed on the three-chain road well off the track, and when broken they would be ready for distribution on the roads where they may be required. If our council and the farmers interested take the matter up, in 10 years' time our roads will be a credit to the district in which we live."

Freeling, June 28.

(Average annual rainfall, 17½ in.)

PRESENT.—Messrs. F. H. Heinrich (chair), Morris, Kuhlmann, Shanahan, H. Mattiske, jun., Elix, Neindorf, Koch, Neldner, A. Mattiske, sen., and G. A. Block (Hon. Sec.).

HARROWING GROWING CROPS.—The majority of members favored the practice of harrowing the wheat crop after it had shown through the ground, but others dissented. A number of farmers in the locality were experimenting with the idea of ascertaining the effect of harrowing, and the results would be watched with interest.

POISONOUS BERRIES.—Mr. Morris drew attention to the fact that the berries of the white cedar were poisonous to horses, cattle, pigs, &c.

Gawler River, June 29.

(Average annual rainfall, 18 in.)

PRESENT.—Messrs. A. J. Bray (chair), J. and B. Hillier, A. J. Davis, C. Leak, W. J. Dawkins, W. Rice, Winckle, G. Higgins, F. Bray (Hon. Sec.).

NOXIOUS WEEDS.—A discussion on this subject was raised by Mr. A. Dawkins, who read an extract from a newspaper. Mr. A. J. Davis drew attention to the need of effective measures for combating noxious weeds, and thought the proposed appointment of inspectors by the Government was a step in the right direction. Mr. W. J. Dawkins said the difficulty was not so much in connection with the weeds on cultivated land, but on the adjoining roadsides and on waste land. There it was an expensive and tedious undertaking to eradicate them. Mr. Rice had found that the seeds of the saffron star thistle would lie dormant in the soil for a number of years. Oats was the best crop to put in where this weed was prevalent, as the crop would outgrow and choke the weeds. Where wheat was planted the weeds found little difficulty in securing a footing, and when cut off by the binder at hay time they shot out again and produced perhaps a dozen flower heads where there had previously been one.

Gawler River, July 29.

(Average annual rainfall, 18 in.)

PRESENT.—Messrs. W. Rice (chair), A. J. Davis, G. Higgins, E. F. Winkler, Richter, J. H. and W. J. Dawkins, J. Hayman, F. Bray, H. C. Dunn, A. M. Dawkins, B. F. Hillier (Hon. Sec.), and two visitors.

LIME.—In a discussion on the subject of adding dressings of lime to the soil, initiated by the Hon. Secretary reading an extract, Mr. A. M. Dawkins said that heavy red clay responded most readily to lime, and this was important, as this class of land had not responded in the same way to fertilisers as the stone land had. Its action on the salts of phosphate perhaps meant more than was generally recognised. Mr. Hayman drew attention to the excellent results which had followed the application of sea shells to the claypans, and Mr. J. H. Dawkins said such soil had been much benefited at the Roseworthy Agricultural College by the addition of limestone rubble.

Greenock, June 29.

PRESENT.—Messrs. W. Roenfeldt (chair), G. O. Tümmel, B. Schultz, R. Tummel, J. Jungfer, E. Handke, C. Liersch, A. Nitschke, B. Nitschke, H. Koch, F. G. Pfeiffer, L. A. Traeger, E. Bockmann, O. Semmler, R. E. Radford, P. Gehling, E. Geyer, O. Krüger, W. B. Siebo, V. Koschade (Hon. Sec.).

IMPORT DUTY ON SUPER.—The proposal that a duty should be imposed on imported manures was discussed at length, and the Branch decided that such an action would be detrimental to the interests of agriculture.

HORSES.—Mr. P. Gehling read a paper on this subject, in which he drew attention to the unreasonable treatment which horses often received at the hands of inexperienced and cruel drivers. Very frequently animals were overdriven at a fast rate, and such treatment was to be severely deprecated. He advocated breaking in horses when they were young, but it was a mistake to pet them, as this frequently led to stubbornness when the time came for breaking them in. If the horse could be brought to understand that its master was also its friend more satisfaction would be got from it. It was a mistake

to use a whip too frequently, as this made the horse nervous. Particular care should be taken to see that the harness fitted, and that it was well cleaned and oiled. The linings of the collars should be occasionally washed with a disinfectant, and the accumulation of sweat, dirt, and hair should be removed. Horses should be well combed and brushed, as this opened the pores of the skin, and it would be generally found that a well-groomed horse kept in good condition and required less feed. The animals should not be put to heavy work immediately after a long spell, but they should be gradually accustomed to it. When they were sweating, after work, they should be well rubbed down. At the mid-day meal the animals should have the collars removed and their shoulders should be carefully brushed. This would go a long way towards obviating sore shoulders.

Saddleworth, June 21.

(Average annual rainfall, 20in.)

PRESENT.—Messrs. R. G. Townsend, F. H. Eckermann, A. J. Caskey, H. Graham, W. Scales, P. Manning, and F. Coleman (Hon. Sec.).

FALLOWING.—In a paper on this subject, Mr. A. J. Caskey recommended the adoption of the three years rotation, if sufficient land to permit of its being carried on were held; otherwise alternate cropping was advisable. It was essential that the fallows should be got on to early; this resulted in the conservation of more moisture for the following season. Red land should not be ploughed whilst it was wet or soft. When ploughing, ridges and furrows which tended to wash into creeks or deep gutters were to be avoided; 3½ in. to 4 in. was a sufficient depth to which to plough red land; black land, however, could be ploughed to from 4 in. to 5½ in., the furrows being from 8½ in. to 9 in. wide. Three or four weeks should elapse between the ploughing and the time the harrows were run over the land, when it should be worked down to a fine tilth. Cultivation should not be to a depth greater than was necessary to kill the weeds. The harrows could not be used too often, and after harvest the roller should be put over lumpy or rough parts. Immediately weeds appeared the cultivator should be brought into requisition. In discussing the subject, some members favored deep ploughing, even to touching the subsoil, a very little of which worked down with the soil in the cultivation by the scarifier would do good. The use of gypsum on the clayey portions of the wheat paddocks was recommended for trial.

YORKE PENINSULA DISTRICT.

(TO BUTE.)

Minlaton, July 13.

(Average annual rainfall, 17in.)

PRESENT.—Messrs. R. H. McKenzie (chair), E. Corroll, T. Giles, S. Vanstone, J. Martin, W. Bennett, and J. McKenzie (Hon. Sec.).

ELEVEN YEARS AS HON. SECRETARY.—Appreciative references were made to the fact that the Hon. Secretary (Mr. J. McKenzie) had carried out the secretarial duties of the Branch for a period of 11 years, during which time he had done much in the interests of the Agricultural Bureau.

ANNUAL REPORT.—The Hon. Secretary read his annual report as follows:—“ In placing before you the 22nd annual report of this Branch, I am sorry to say that it has been one of the poorest years on record. At the last annual meeting we had 12 members; at present we have 13. We have held seven meetings, with an average attendance of four. Four good papers have been read and discussed. I have to thank the members who read papers. They have done their duty, but the discussion has been disappointing

to them on account of the poor attendance. As this meeting has been called to bury or reorganize the Branch, I wish to put before you what I consider some of the reasons why our Branch is not more successful. The members do not realise their duties. It is, in my opinion, a privilege as well as a duty to belong to the Bureau. The member that drops in once in two or three months to see what is doing is no good to any Branch. I want the members to understand that the Bureau is supported by the taxpayers, and is one of, if not the, best agricultural institution in the State. Members, as you know, are proposed by the Branches and approved by the Advisory Board, which is appointed by the Government. A person should consider that he owes a duty to his country when he becomes a member. The Advisory Board is guided to a great extent by the opinions of Branches, and often the Government is guided by the Advisory Board; therefore, when one becomes a member of the Branch one's influence can be used right through the State. Remember that the taxpayers' money is being spent on you as advisers of the State. The Hon. T. Pascoe considers the Bureau as being a most important factor in the improvement in the agricultural methods in South Australia. Professor Lowrie says the Bureau enables the department to ascertain what the farmer most needs, and many other authorities say that it is a most valuable institution. There are about 132 Branches; about 20 more than there were last year, and the members get the opinions of experts on various subjects, and scores of suspicious plants are identified by them. Some farmers say they can get the *Journal* for 1s. per year and get all the information. Quite true; but if they were all hangers on, where would the information come from? They are satisfied to sit quietly by and get the result of the other fellows' brains for nothing. Members! be up and doing. There is work for all, and our country needs our help. In our district we should have a real live Branch with 25 or more members if the members put the right spirit into the thing. Alter the time of meeting to evening. Do anything; but do not let the Branch die for want of energy. Try to get the young men to join. We go into recess in harvest and seeding because we have not time to attend meetings; yet, I venture to say, if a football match were held in the middle of harvest almost every member would be there. At this time of the year nearly every Saturday is taken up with football. Perhaps we could alter the time of meeting to some other time or evening. I see that some of the recently formed Branches have as many as 60 members. If half that number attended they would have a good time. If a member, when writing a paper, knew that there would be 15 or 20 there to hear him, he would endeavor to give them his very best, and would himself benefit by the exchange of opinion. I see no reason why this Branch should give up. I think it would be a distinct loss to the district, and the members would fall short of their duty to the district, to the country, and to themselves. Remember that we are living in one of the most progressive parts of the State, and our opinions are sought after and valued by many new settlers in other parts. It is also very evident that the opinions are sought after and valued by all our officials and by the Government. A few extracts from the history of the Branch may be of interest to the present members. The Branch was opened on January 4th, 1890. Mr. Tonkin presided and Mr. C. Smith was Hon. Secretary. I notice Mr. S. Vanstone was present at that meeting, and this gentleman has been one of our best members. Mr. Smith was secretary for two years, Mr. Jas. Correll for nine years, Mr. Mayer for three months, and the present occupant has carried out the duties for 11 years. There have been about 52 members of the Branch. I am of the opinion that members should have the objects and the constitution of the Bureau read occasionally at their meetings. The last paragraph of this pledges the Branch to do everything in its power to carry out the objects of the Bureau. I would also suggest that the officials be asked to have the objects and constitution printed in the *Journal* continuously. In conclusion, I would urge on members that the only way to make the meetings successful is for every member to come to the meetings prepared to discuss any or every subject that is brought forward, and come prepared to introduce a subject every time. If we consider we have nothing to learn, then there is more reason why we should teach others. Surely we are not going to keep our knowledge to ourselves. We would only be doing our duty by letting the world know that there is a limit, and that we have reached it."

Pine Forest, June 27.

(Average annual rainfall, 13in.)

PRESENT.—Messrs. D. Carmen (chair), G. Inkster, A. Nelson, C. Schultz, W. Attenborough, S. Barr, A. Hewett, and R. D. Goodridge (Hon. Sec.)

SHEEP ON SMALL HOLDINGS.—In a paper on this subject Mr. D. Carmen said that if fat lambs were to be profitably raised they must be well fed, and it was therefore better

to have the farm somewhat understocked than otherwise. A lamb that received a check in the early stages of its growth would never make a prime freezer. It was a mistake to feed off the paddocks too bare, and he would prefer to have some dry grass left to shelter the young grass after the rain had caused the seed to germinate. The Shropshire cross would be found to be more easily fattened than the Merino, but against this was the price received for the wool of the latter, and the deduction which had to be made for the number of rejects in the former. Four to six tooth ewes should be bred to four-tooth rams. At this time of the year especial attention should be paid to the sheep: there should be water in every paddock, and frequent changes of pasture were necessary. Lambs should be tailed when they reached the age of two months. Well cared for, they should be ready for freezing at five months. In discussing the subject, Mr. Inkster said he preferred the Shropshire cross for fat lambs, as they grew faster, and any reject could be made use of on the farm. Mr. Hewett favored the Lincoln cross. Mr. Schultz advised the growing of green feed, such as peas and maize to top the lambs off. Twenty acres of peas would very materially assist in fattening 200 lambs.

WESTERN DISTRICT.

Elbow Hill, June 29.

PRESENT.—Messrs. Cooper (chair), E. Wake, H. and L. Wheeler, C. Jacobs, E. Story, G. F. Wake (Hon. Sec.), and two visitors.

FIELD TRIALS.—In a paper on this subject Mr. Jacobs said the chief benefit of field trials was that they gave agriculturists the opportunity of comparing the efficiency of various implements. It was generally found that insufficient time was allowed for the satisfactory completion of arrangements in connection with the trials, and the writer was of the opinion that arrangements should be taken in hand 12 months before the date fixed for the trial. The co-operation of Branches in this connection was likely to be productive of better results than generally followed the efforts of a single Branch to carry out a trial. The Hon. Secretary thought little good resulted from field trials, as most of the implements which were worked were just out of the factory, and they were attended by an expert during the competition. It was reasonable to expect any implement to do good work under such circumstances. Mr. E. Wake thought more good would be attained if the Branches were to give better support to the agricultural shows.

Green Patch, July 1.

(Average annual rainfall, 26in.)

PRESENT.—Messrs. F. Gore (chair), G. Sinclair, J. Sinclair, sen., C. Parker, E. Chapman, C. J. Whillas (Hon. Sec.), and one visitor.

MANURES.—The following paper on this subject was contributed by the Hon. Secretary:—"The reactions that take place in the soil in connection with the growth of plants are very complex and are not yet all thoroughly understood. However, enough is known of them to greatly aid the farmer. Experience and field tests are also necessary to determine the most profitable system of treatment for each different soil, crop, and climatic condition. Fertility is in a great measure due to the power of a soil to retain plant food. The presence of humus, iron oxides, clay, and lime all greatly assist this power. Virgin soils are generally rich in plant foods; but when the crops from these are continuously taken off the soil, a time soon arrives when it pays to return at least a part of the plant food required by the crops grown. The excrements of the men or the animals consuming the crops would, of course, be the most complete return to make, but under farm conditions this can seldom be profitably done, whereas it has been found that returning by

chemical manures some necessary portion of the plant food required is often highly profitable. Experience shows that the most profitable chemical manures to use in this way are nitrogen, potash, and phosphates. For cereal growing under Australian conditions, experience and thousands of field tests have shown that the phosphates are the only payable plant foods to add to the soil. Australian soils, aided by the climate and the system of working, apparently keep up an abundant supply of potash and nitrogen. The latter is also probably helped by the clovers growing on the soils. In a dry climate, well-worked bare fallow increases the available nitrogen in a soil by the absorption from the air and rainwater of nitrogen compounds, and by the oxidation of these compounds and of the humus of the soil. This oxidation is due to the action of bacteria, which require warmth, access of air to the soil, and a little moisture. It changes the nitrogen compounds to a form that can be taken up by the plant rootlets. Apart from this, working the fallow breaks up the soil particles, make more available other plant foods, and gives the plant rootlets better access to these foods. The available nitrogen is present in a very soluble form, and bare fallow on a light soil with a heavy rainfall will result in a serious loss of nitrogen. A clay soil has more power of retaining its nitrogen. Most soils contain an abundance of plant foods, but generally only a very small portion of this is in a form available to the plant. Tilling the soil increases this portion, and the addition of a small quantity of necessary available plant food may help to start the plant and put it in a condition to attack and make use of some of the less available plant food in the soil. A fertile soil may, in the top 9 in. contain phosphates equivalent to many tons per acre of super., and still require the addition of a little water soluble super. to grow a crop. Superphosphate, the most important manure to the Australian farmer, is mainly a mixture of monocalcic phosphate with gypsum (calcium sulphate) and impurities derived from the original mineral. It is manufactured by treating very finely ground phosphoric rock (insoluble tricalcic phosphate) with sulphuric acid, resulting in water soluble monocalcic phosphate and gypsum. In practice some of the phosphate is left unchanged, otherwise the manure would be too acid, and, therefore, sticky and poor running. If the super. is kept for any length of time there will be some reversion to a citrate soluble form, unless there is an excess of sulphuric acid at the start. Some of the imported manures apparently are made too acid to prevent reversion, and hence their stickiness. Should the original rock contain oxides of iron or alumina there will be a reversion to a citrate soluble phosphate in proportion to the amount of these impurities. Citric acid has about equal solvent power as have the organic acids formed in the soil by plant roots, and is therefore used as a standard for commercial purposes. The citrate soluble phosphate of a manure is of considerably less immediate value to the plant than the water soluble phosphate. The percentages quoted by super. manufacturers are given in terms of tricalcic phosphate, 36 per cent. super. meaning that the manure contains 36 per cent. of tricalcic phosphate rendered soluble. This would be equivalent to about 17 per cent. of phosphoric acid. It seems to me it would be less confusing to give the percentages in phosphoric acid. Almost all soils have great retentive powers for phosphates, and losses by leaching will not take place unless the soil is quite destitute of humus, iron, lime, or clay. The water soluble super. drilled in the soil is, with the first moisture, changed to a citrate or an insoluble form. However, the chemical action that takes place so subdivides and distributes it through the soil particles that it is easily available to the plant. No methods of mechanical grinding and distribution could possibly put an insoluble phosphate in the soil in a form so available to the plant as is done by this chemical action; i.e., first the dissolving of the phosphate in water, and then the precipitation of it again in the soil as soon as it comes in contact with the necessary base, such as the compounds of iron, &c. Experience proves that it is only the water soluble super. that is of immediate benefit to the crop, and as in many cases there is ample insoluble phosphates already in the soil, it would appear hardly profitable to add an insoluble phosphoric manure. However, some soils may be short of phosphates in any form, and here heavy dressings of insoluble very finely ground phosphoric manures would no doubt prove profitable in the long run. Thomas phosphate is a bi-product of the basic process of steel manufacture from pig iron containing phosphorous. It is practically a mixture of tetracalcic phosphate and quick lime. It is greatly used in England and Europe, costing about 40s. per ton for 16-18 per cent. soluble phosphoric acid, and perhaps 20 per cent. of lime. This phosphate is very finely ground, and is as available practically to the plant as monocalcic phosphate, also benefiting many soils by the lime which it contains. The following are some of the effects of adding quicklime to a soil. On a soil destitute of lime it would supply a necessary plant food. It makes more available some of the plant foods already in the soil. On acid soils it neutralises the organic acids in the soil, i.e., sweetens the soil, stimulates the action of useful bacteria in the soil, and improves the physical condition of both clay

and sandy soils. However, there is often ample lime in a soil, and Australian experiences do not, I think, show much benefit from liming. Regarding field tests for manures on wheat crops, I have carried out a number during the past seven years. I found that mineral super. and Thomas phosphate give about equal results. Guano is of little use to the immediate crop. Lime, potash, and nitrogen manures show no benefit whatever to the crop. I prefer 36 per cent. super. to any of the lower grades. These tests were in a deep sandy loam over clay subsoil, with an average rainfall of 26in."

Kopplo, June 27.

(Average annual rainfall, 17in.)

PRESENT.—Messrs. G. B. Gardner (chair), T. Brennand, H. Thompson, J. Newell, G. and M. Howard, T. R. and M. T. Gardner (Hon. Sec.), and two visitors.

CARE OF WORKING HORSES.—The Hon. Secretary contributed the following paper :—"At this season of the year most farmers are busily engaged tilling the soil, and during the period extending over sowing operations the horses have to do the hardest work they are called upon to perform. To enable them to go through the work quickly they should be in good condition and in good heart. They should have at least two months' spell after the harvesting work is finished, and should be fed a little every day, even when not working. I prefer good wheaten hay, chaffed, with a fair amount of corn ripened in it. If Small's Early variety is available, so much the better. When horses are working hard they should be well and regularly fed, and should have not less than 35lbs. of chaff a day with 3lbs. of oats and 2lbs. of bran in the 2lbs. of chaff at dinner time. If they are kept well, one hour's actual feeding time should be long enough for dinner, provided the feed is rich and good. One hour and a half should be allowed for feeding before they are put to work in the morning. They should be allowed to go to water fairly often, and it is better to provide a trough than to turn them loose into a waterhole or dam. In the winter time especially, they should be provided with a warm dry stable, and I would rather have them all loose with the run of a good sized yard than tie them up. The collar plays an important part in the horse's work, and they will work far better in collars that fit them than in those that have to be packed up with bags. A mistake is often made when purchasing collars in not allowing for the horses losing condition. Collars should be cared for. Horses will not work so well in strange collars, and often contract sore shoulders when a new one is put on them. I prefer check-lined collars, stuffed with horsehair, which should be repaired immediately they become ragged. The farmer should be able to reline his collars with a piece of bag and stuff them as required. Too much care cannot be given the team when working on rough land. If the teamster is a careful and experienced man he is always on the lookout for small things that may get out of order in connection with the harness." A good discussion followed the reading of the paper. Several members thought oat chaff better than wheaten chaff for feeding horses. One member thought 3lbs. of oats rather much for one feed, and would distribute that quantity over the three feeds. Mr. Brennand expressed the view that less trouble would be experienced with sore shoulders if steel collars were used.

Miltalie, June 28.

(Average annual rainfall, 14½in.)

PRESENT.—Messrs. J. P. Story (chair), T. W. and E. Story, E. P. Smith, A. R. S. Ramsey, J. S. Jacobs, T. A., A. M., and M. H. Wilson, H. R. Jacobs, F. Alm, P. G. Wilson, F. Jacobs, W. E. Hier (Hon. Sec.), and four visitors.

EXPERIMENTS ON THE FARM.—The paper on this subject, read by Mr. P. G. Wilson, and printed on page 1292 of the July issue, was discussed. Mr. T. A. Wilson stated that though analyses of soil were very useful, the farmer could only definitely decide the strength or weakness of his land by actual experiment. Mr. J. S. Jacobs believed the depth of ploughing should be determined by the soil. When it was not too wet, fairly deep ploughing should be the rule. Land intended for fallow could advantageously be worked in March with light implements. Mr. E. Story thought it necessary to sow thickly in wet districts, and thinner in drier parts. These and other matters could be determined by the farmers conducting tests on their holdings.

FARM OUTBUILDINGS.—Mr. T. F. Alm contributed the following paper :—"My attention has often been drawn to unsightly old sheds which are allowed to remain on farms. For several reasons I prefer a shed with a straw roof. It tends to keep a more even tempera-

ture than is the case with an iron roof. The former will be found far more serviceable on a stable, as it will be warmer in the winter time and cooler during the summer months, which is most important. Of course, in a country with a low rainfall and an insufficient water supply, an iron roof will be found most serviceable. When building a stable for horses I would procure forks 8ft. 6in. long for the front and back rows, and put them 1ft. 9in. in the ground. The inside row of forks should be 2ft. higher, in order that the water may be run off. The forks should be placed 12ft. apart; this provides stands for two horses. If possible, I would build a shed with good mallee rails instead of pines, as the latter are more liable to break when dry. Cover the roof with 6ft. netting wire, as it will keep the straw smooth; the wind cannot do so much damage, nor can the fowls scratch holes in it. If a roof is secured with ordinary fencing wire it will become uneven, and water will run in and rot the straw. It is advisable to have the shed facing the east, as there is less likelihood of rough weather from that quarter. The harness room should be in a position convenient to the stable, so that the horses can be harnessed while they are still feeding. The harness should be hung up on pegs in the wall, instead of over a rail, as is usually the case. The collars have to be opened every time they are hung on and taken off the rail, and they are thus more likely to be broken. Time and labor will be saved if the chaff is handy. The implement sheds should be built on a fairly level piece of ground, as it is generally a nuisance to get implements in and out of a shed if it is on the side of a hill. A large barn is also needed in which to stack the seed wheat and manure. I have frequently seen the seed wheat provided with no shelter whatever. The barn should be built with a stone wall and a good concrete floor, and it could then be partitioned, so that the wheat could be emptied out of the bags. The mice generally cause a good deal of damage to the bags when they are stacked. The men's room is very often in a very dilapidated state, and more attention should be paid to this than has been the case in the past. If better accommodation were provided, there would not be such a scarcity of farm labor. If an iron building 12ft. by 10ft. were erected, and lined with matchboard and a fireplace provided, this should make comfortable quarters for two men."

Petina, June 29.

(Average annual rainfall, 12½in.)

PRESENT.—Messrs. W. Penna (chair), F. Barnes, J. H. Wharfe, E. Keeley, D. T. Kenny, C. J. Howard, J. Bascombe, G. A. Newbon, W. H. Howard, W. Kieley, J. Souther (Hon. Sec.), and four visitors.

SCRUB FARMING.—An interesting paper on this subject was read by Mr. D. T. Kenny, in which he dealt with the hardships that the scrub farmer encountered. The trouble experienced in securing a good stubble burn and the depredations of the rabbits were factors which exercised the landholder very considerably. A great deal of difficulty was usually experienced in securing a water supply, and often when tanks were built they would not hold.

BUCKBUSH.—Mr. Kenny said that buckbush stacked at the proper time made good feed. The method of stacking adopted was to place a layer of straw on the ground, on this a layer of buckbush, then again a layer of straw, until the stack was finished. A farmer in the Murat Bay district had used this for fattening ration sheep with good results. Members generally agreed that, stacked at the proper period of its growth, buckbush was a good fodder.

Shannon, June 29.

PRESENT.—Messrs. W. Proctor (chair), J. Fleming, M. Cronin, H. Proctor, L. A. Wilkins, W. Wemyss, C. Wemyss, M. T. Cronin, W. Williams, F. Proctor, V. G. Gordon, J. J. Cronin (Hon. Sec.).

TREATMENT OF HORSES' SHOULDERS.—The following paper was read by Mr. W. Williams:—"The horse is the mainstay of the farm, and it is the duty of every driver to see that it is well cared for and well fed and that the harness is well looked after, so that the animal may work in comfort. To keep a horse's shoulders free from sores from one year's end to another is a difficult matter, and very often it is more than the ordinary driver can do. Prevention is better than cure, and we may keep very close to the spirit of this old proverb by carefully following a method something after this style, which in

my experience seems to be well worth the carrying out: Keep the horses' shoulders well brushed every morning and dinner time, so that no dry sweat and matted hair collect together. Do not use branbags under the collars; spend a few shillings on leather false collars and keep them well oiled with first-grade neatsfoot oil. Procure Fairplay hames with sliding draught, so that you may be able to adjust the hame hooks to an even height and give an even pull to each shoulder. Remember that one hook an inch higher or lower than the other will cause a lot of trouble, and it is almost impossible to cure a sore shoulder under these conditions." In discussing the subject Mr. Fleming said that the use of the branbag in the collar was not altogether to be despised, as he had tried it with very good results. Mr. Wilkins preferred leather false collars, which he would keep well oiled with raw linseed oil.

Utera Plains, June 29.

(Average annual rainfall, 14in.)

PRESENT.—Messrs. A. Ramsey (chair), A. Venning, W. Gale, T. C. and H. C. Hornhardt, G. and A. Barber, G. Bilney, W. Stephens, J. and M. Abrook, N. Guidera, Fraunack, H. T. Hornhardt, M. Hunt, H. Hill, F. H. Harwood, G. Brinsley, W. Lee, P. Sinclair, R. Hill (Hon. Sec.), and a large number of visitors, including ladies.

PAPERS FROM THE "JOURNAL."—Five members read as many papers from the *Journal of Agriculture*, and a general discussion followed each. Speaking of horse-breaking, Mr. Venning thought colts broken in with the open bridle were not so timid as those broken to winkers. Mr. W. Gale thought the stripper the best implement to use when mousing a young animal. Other members preferred to put the animal in the drill for this part of his education, as he then learned to turn both ways. One member spoke of the value of a blacksmith's shop on the farm. He had had one for four years, and it had been a profitable investment. Farmers who had sons should send one of them to work with a smith for a few months to pick up some wrinkles in the business. Knowledge thus gained would be of service again and again.

EASTERN DISTRICT.

(EAST OF MOUNT LOFTY RANGES.)

Forster, June 22.

(Average annual rainfall, 10½in.)

PRESENT.—Messrs. W. Searle (chair), J. and G. Searle, J. G. and R. Whitfield, F. Johns C. Hayman, T. Retallack, W. J. Sears (Hon. Sec.), and two visitors.

USEFULNESS OF THE BUREAU.—Mr. J. Searle expressed the opinion that the Agricultural Bureau was doing very little good, as members attended the meetings, discussed various subjects, but did not put the ideas gained there into any practical effect. Mr. J. G. Whitfield thought the Bureau was a splendid institution. A great deal of information was secured from the *Agricultural Journal*, especially by the young men. Mr. Searle said through the medium of the Bureau members secured an insight into the methods adopted in other parts, and could compare these with their own, and follow the most economical. Mr. Hayman had learned more about agriculture at the Bureau meetings than anywhere else.

Lameroo, June 29.

(Average annual rainfall, 16in.)

PRESENT.—Messrs. E. J. Troubridge (chair), O'Connor, Leckie, Lehman, C. R. Eime, Thyer, Sinclair, Ross, Kain, Batten, A. J. A. Koch (Hon. Sec.)

DAIRYING.—Mr. S. R. Sinclair read a paper on this subject, in which he expressed the view that if systematically carried out dairying should be a profitable venture in this

district. The first essential was to secure a pure-bred bull from a cow of known milking strain. If possible a few pure-bred cows should also be secured, but where this could not be done the bull would in time improve the herd. The best cow to keep was the Jersey, as this animal did well and yielded a liberal supply of milk. It would be found that the cows of this breed would stay in milk right up to the time of calving, but it was advisable to dry them off a month beforehand. The Ayrshire was a very good milk and butter cow, and it had the advantage of being larger than the Jersey. It would be found more saleable when the milking period was over. It should not be forgotten that the cow should receive enough good feed to keep her in condition, as well as to provide for the drain on her constitution in connection with the milk yield. Lucerne should be grown, and enough hay should be carried to provide feed right throughout the year. Crushed oats should be mixed with chaff, and this could be damped with molasses mixed with water. The feeding should be done regularly, and the animal should be given as much as it would eat without any waste. Proper housing accommodation should be provided, and although the cows could be rugged for protection against the weather, it would be found that it paid better to spend this money in the purchase of timber and iron for shed-building. In discussing the paper Mr. A. Ross said he preferred Holsteins for this district, as they were more hardy than the smaller cows. Mr. C. R. Eime had used crushed wheat with hay and chaff, and found it a good milk-producer. Mr. O'Connor pointed out that during the drought period some years ago the dairying industry was the mainstay in a great many instances around Hawker, where many farmers entirely gave up wheat-growing. In Denmark co-operative breeding was practised, and many advantages were gained by it. Mr. W. M. Thyer was of the opinion that these parts were rather too severe for the smaller and more delicate breeds of cows, and thought the Ayrshire-Holstein cross would suit admirably. Mangolds chopped up and mixed with molasses made excellent food. Mr. E. J. Troubridge was of the opinion that regularity was the essential feature in connection with dairying, and it was immaterial what breed of cows was kept so long as they were good.

Monarto South. June 29.

PRESENT.—Messrs. A. P. Braendler (chair), B. Hoff, R. S. McDonald, R. E. Anders, E. Tillbrook, J. G. H. Paech, J. and H. Frahn, F. C. Thiele, G. A., E., and R. Hartmann, G. Patterson, C. F. Altmann (Hon. Sec.), and eight visitors.

RABBIT-PROOF FENCING.—Mr. E. Tillbrook, in a paper on this subject, stated that before rabbit-proof netting was put on to a fence care should be taken to see that the posts of the latter were in good order, and that new struts were put in wherever necessary. All the wires should be tightened and a barbed wire should be run along the top. Forty-two inch netting of the 1½ in. mesh should be buried in a trench to a depth of 3 in. or 4 in. in light soil, or 2 in. or 3 in. in harder land. The end of the netting should be fastened to the strainer with ½ in. large-headed nails, and a fork handle or crowbar could be used to unroll it, care being taken that it was tightened as it was being put up. At every interval of 3 ft. the netting should be fastened to the top wire with small galvanized wire. Where a rabbit-proof fence was to be erected 3 ft. 6 in. posts could be put in at a distance of 30 ft. apart and two T-iron standards put equidistant between these posts, the flat side of the standards being kept towards the netting. At intervals of 200 yds. strainers should be put in. Where, however, big cattle were to be provided for posts should be put in 21 ft. apart, with one iron standard between them. One barbed and three plain wires should be used. The former should be on top, with the first plain wire 4 in. below it. The lowest wire should be placed 12 in. from the ground. Mr. McDonald favored the 1½ in. mesh, as small rabbits would get through the 1½ in. and again stock the ground that was netted off. Instead of putting it in a trench he preferred to lay about 4 in. or 5 in. of the netting on the surface out towards the rabbits, and pack it down well with stones. As rabbits would always burrow close to netting that would prevent them getting down. Members agreed with Mr. McDonald's views, and although the method was the most expensive, it was considered the most effective. Mr. R. E. Anders read the paper on the destruction of rabbits which appeared on page 1085 of the May issue of the *Journal*. Three months (the time specified in the Rabbit Destruction Act) was, in his opinion, too long for the simultaneous destruction of rabbits, as some landholders started at the beginning of January and others left it till the end of March, thereby practically compelling their neighbors to kill their rabbits. The general opinion was that one month was quite long enough. As it was necessary that the rabbits should be destroyed during the first three months of the year, while the grass was dry, it should be left to the district councils to fix the month for the respective districts. February was most suitable for this district.

Monarto South, July 27.

PRESENT.—Messrs. A. P. Braendler (chair), B. Hoff, J. G. H. Paech, E. Tilbrook, F. C. Thiele, G. Gogol, B. J. and H. Frahn, G. and R. Paech, A. Schenscher, R. S. McDonald, C. F. Altmann (Hon. Sec.), and four visitors.

WHEAT-GROWING.—Mr. F. C. Thiele supplied the following estimate of the cost of wheat-growing in the district. The value of the property was estimated at £5 per acre, a 5 per cent. rental equalling 10s. The following items were allowed for:—Ploughing, 4s. per acre; twice cultivating, 5s.; twice harrowing, 1s. 6d.; drilling, 2s.; rolling, 6d.; super., 4s. 6d.; seed, 3s. 6d.; harvesting, 4s.; cornsacks, 2s. 6d.; carting, 1s. 3d.; depreciation of stock and implements by 10 per cent. of value, 5s.; making a total of £2 3s. 9d. On an average crop of 15bush.. sold at 3s. 6d., the income would be £2 12s. 6d., which, after deducting the cost of production, viz., £2 3s. 9d., left a net return of 8s. 9d. per acre. The cost of producing 1bush. of wheat was 2s. 11d. In discussing the subject some members expressed the view that the costs estimated in the paper were too high, and that a 15-bush. crop should leave a bigger profit than 8s. 9d.; but the majority were of the opinion that the cost of working the land as stated by Mr. Thiele was a fair average for the district. It would be interesting to have the opinions of farmers in other districts, with a view to comparing the cost of production of the wheat crop in different localities.

Monteith, July 6.

PRESENT.—Messrs. Travers (chair), Rowan, Connell, Ferris, Clark, Wells, Smith, Martin, Frazer, Bradford, Magor, Gunn (Hon. Sec.), and nine visitors.

THE MILK SUPPLY FOR ADELAIDE.—The following paper was read by Mr. Rowan:—“I have no hesitation in saying that the milk supply of the city should be under Government control. Purity should be the hall-mark. The dairyman and the consumer alike should have the independent assistance of a chemist and bacteriologist, and if such were provided greater confidence would be gained in the supply and a keener demand created. In South Australia, with its warm climate, the introduction of modern methods of improving the milk supply is sadly needed; but the consumer gives no encouragement to the farmer to improve the quality. The attitude is to favor cheapness, and the householder forgets that as a staple food milk has a marked variability in composition and feeding properties. In the nourishment of infants no special precautions are taken to meet the requirements of health, and no doubt many deaths take place through the neglect of parents to provide against the introduction of infant diseases contracted through the agency of impure milk. Aeration of milk is especially necessary in the country, and the introduction of a suitable appliance has been strongly recommended in order to demonstrate to milk suppliers the necessity for the aeration of milk directly after the milking process. The Lawrence cooler is very useful, water being used in this for the cooling. It takes off all the animal heat, and adds six hours keeping quality, which is of great value where milk has to travel by road or rail. Considering the prices obtaining in Adelaide, the producer should receive not less than 1s. per gallon for his milk.” A number of demonstrations in milk-testing were given by Mr. Rowan, which were greatly appreciated.

Moorlands, June 28.

PRESENT.—Messrs. L. Spurr (chair), J. Schubert, R. Neumann, A. H. and E. Miatke A. Oppatt, A. Maczkowiach, R. Spurr (acting Hon. Sec.), and one visitor.

IMPORT DUTY ON SUPER.—Considerable discussion took place concerning a proposal recently made that an import duty should be imposed on superphosphates. A resolution was unanimously carried protesting that such action would seriously damage the producing industries of the State.

LIMING LIGHT SOIL.—An extract on this subject was read by Mr. R. Spurr. In discussing the matter he explained that in this district there was a considerable amount of limestone available, which could be utilised if a little time were spent in burning the lime. Mallee roots were also there in abundance to provide the necessary fuel. There was a vast difference between limestone and carbonate of lime, and he thought the former in its natural state had no effect, whereas, if it were burnt and slaked it would undoubtedly be beneficial to the soil in this district. Mr. Oppatt thought that more would be done

by the application of nitrate of lime than would be the case if carbonate of lime were applied. The former was much quicker in action than the latter, and he was conducting extensive experiments with nitrate of lime with the idea of ascertaining its effect.

Parilla Well, July 4.

PRESENT.—Messrs. J. E. Johnson (chair), J. and W. Flavol, D. and J. Ferguson, E. H. Leak, H. Leak, J. W. Johnson, G. and B. Pahl, T. Burford, F. Foreman, L. G. Neville (Hon. Sec.), and three visitors.

CARE OF FARM MACHINERY.—Mr. J. W. Johnson read a paper on this subject, in which he drew attention to the necessity of carefully tightening and oiling machinery directly it was received. Sand would be found to work into the bearings unless care was taken. A machine that was composed partly of wood should be protected from the influence of the weather, as difficulty would be experienced with the wood warping and twisting. Wherever practicable the farmer should erect an iron shed for his machinery, and on wet days his time could be well spent in cleaning and repairing. The woodwork should be frequently painted, and this applied especially to wagons and drays. Every farmer's outfit should include a small set of blacksmith's tools, with bellows or a portable forge, an anvil, drills, tongs, iron-cutters, round and flat iron of various sizes, together with such other tools as were found necessary. The handy man could soon learn to save a good deal of trouble and expense by straightening tyres, drawing shares, making S hooks, eyebolts, &c.

Parrakle, July 27.

PRESENT.—Messrs. F. J. Dayman (chair), C. E. Hammond, R. L. Beddome, W. Threadgold, A. C. Hamiester, R. F. Brinkley, A. J. Beelitz, M. J. Kildea, N. Good, O. Heinzel, F. W. Randall, A. F. and F. S. Dayman, J. G. Temby, H. Denver (Hon. Sec.), and seven visitors.

TREATMENT OF VIRGIN SOIL.—Mr. A. S. Johncock read the following paper:—"New land, especially in the mallee districts, has a tendency to sourness, which must be removed before any hope of growing an average crop can be entertained. Where the landholder has green scrub it is a comparatively easy matter to sweeten the land, but when there are three or four year old bushes and dry sticks from the last fire, it is a very different proposition. In the first instance the fire will do practically all the sweetening required, but in the second nothing but thorough working will do it, and there is a considerable amount of work required where sticks, low bushes, and green undergrowth prevail. My opinion in regard to working the land is, always to fallow it the first year, using a share plough. The plough not only turns up the soil better than cultivators, but it also pulls out a considerable percentage of the stumps in addition to pulling out, or at any rate, breaking the thin roots which are near enough to the surface for it to get hold of. Plough about 3½ in. or 4 in. deep, throw the ground up as roughly and as loosely as possible in order to allow the sun to play on it, and to allow the air to penetrate it thoroughly. Want of air is very frequently the cause of this sourness. Other causes are the various acids which get into the ground from the scrub and undergrowth. Fallow early, and so give as much time for the land to sweeten as is possible. If it is a stiff clayey land it will always pay to give it a dressing of lime, this will help the sweetening, keep the ground loose, and also act as a manure. Cultivate the fallow as late in the spring as can be managed. Make the top as fine as possible. The finer this is worked the more moisture will be conserved. For this reason I favor harrowing fallow. The harrows will leave a smoother surface than a cultivator, and we must have a fairly even and finely-worked surface to stand the heat of the summer and conserve moisture. The more the harrows are used the better will be the results. Cultivate about 2½ in. deep for a seedbed, always taking care not to cultivate as deep as the land was at first ploughed. Leave what is underneath for the next ploughing to turn up. If the crop is sown dry, harrow behind the drill. This method, carefully carried out, will insure a satisfactory yield, always supposing the atmospheric conditions are favorable." The majority of members favored the use of the share plough. It was a good plan to cultivate and harrow after ploughing, and rather than crop new land which had not had a good burn the first year, it should be fallowed.

COMMENCING FARMING IN THE PINNAROO DISTRICT.—The following paper was read by the Hon. Secretary:—"I would start work on a mallee farm in the Pinnaroo or Loxton district by erecting a galvanized iron house, just large enough to live in, and a shed to store chaff, super., &c., in. The next thing would be to get a water supply. I should put the bore down and case it with strong galvanized downpipe, soldering all the joints as I put them down. This only runs into about one-third the cost of steel casing, and is just as durable. A windmill and pump are necessary. I do not believe in engines of any kind for pumping water for stock or domestic use. No matter how economical they are they run into a considerable expense in a few years, while the windmill costs practically nothing. I would then get a team of bullocks and a roller and a truck or two of chaff and roll as much of my block as I could, getting over the best land first. If possible, I would roll the whole block, excepting the tops of sandhills and a few patches for firewood and shelter. I would then sell the bullocks. If I had all or nearly all of my block rolled I would have no trouble with clearing burnt scrub. Everyone who has had to clear some of that knows the labor and expense attached to it. If fortunate enough not to have my scrub burnt by scrub fires in summer, I would burn about 400 acres, selecting a good hot day with a fairly strong north wind. I would then get a team of six horses and a Gaston Duplex 12-disc cultivator and a 17 or 19 disc drill and disc the solid ground, and as soon as the rain came would go on drilling and put it in, using about 40lbs. of super. to the acre. About 300 acres of wheat and 100 acres of oats would be the crop. After seeding I would pick the stumps and rubbish off 40 or 50 acres for hay, and erect a fence around the crop. I would cut as much hay as possible the first year, as a bit to spare is better than not enough. I prefer the harvester, and would use a chaff carrier and save as much of the cocky chaff as possible. When mixed with oats it makes good feed and helps the haystack to last out longer. As soon as wheat-carting was finished I would fire rake the stubble. I have a fire rake 25ft. wide, and would not recommend a small one to anyone. The larger the rake the quicker it gets over the ground, and it does much better work by keeping a larger fire going. I would then burn another 400 or 500 acres of the scrub left from last season, and treat it in the same way as that cropped the previous year: but would sow the oats on the stubble ground. If I had only one team, the second year I would fallow that portion of the stubble land not sown with oats, using the disc cultivator and going over it several times before harvest. The greatest drawback in this district is the scarcity of horsefeed, but if plenty of oats is grown and cocky chaff saved, in addition to a fair quantity of hay cut, the expense will not be so great. I would not recommend anyone to bring old horses here. Rather have them on the light side, if studying expense. If the scrub were burned the first year, I would simply drill it in. The second year I would sow half of it after disking well, and after seeding would fallow the remainder." In discussing the subject, some members thought it inadvisable to roll more than 500 acres, as difficulty would be experienced in controlling the shoots on a larger area. Mr. Temby would roll as much as possible and would fallow that which he could not put under crop the first season. He would use horses for rolling, and a stripper and power winnower for harvesting. The Chairman favored getting rid of the scrub as soon as possible, and would fallow that portion which he could not crop. If there were plenty of grass, &c., about, he preferred using bullocks for rolling; but if he had to feed them he would rather use horses. The harvester was best for taking off the crop. Mr. Hammond would use horses for rolling. In replying, the Hon. Secretary said it was better to get the scrub down than to have a lot of black sticks to deal with. Burnt scrub was expensive to clear. If a man had more land cleared than he could crop and fallow, some of his neighbors would, no doubt, be pleased to put it in. It was safer to use bullocks for rolling scrub, for if an animal were accidentally killed, the loss represented would be only about £8 or £10, whereas if a horse were destroyed the loss would be nearer £30.

Pinnaroo, June 22.

PRESENT.—MESSRS. B. L. Harfield (chair), F. G. Bonnin, H. E. Dibben, F. H. and K. Edwards, H. Fewings, L. M. Ferguson, F. Hunt, H. C. Hill, W. H. Kelly, H. Ledger, C. Lee, J. Lethaby, F. Laycock, M. McCabe, B. H. Nash, E. H. Parsons, W. Venning, Geo. and W. Wilson, P. H. Jones (Hon. Sec.), and one visitor.

HOW TO IMPROVE THE WORK OF THE AGRICULTURAL BUREAU.—The papers on this subject read at the last Annual Congress were read and discussed by members. It was generally admitted that homestead meetings and the wheat-growing competitions—the plots of which could be inspected by members—were far more beneficial and interesting than the holding of social evenings as a means of varying the year's programme.

WHEAT-GROWING, ETC., WITH THE AID OF ELECTRICITY.—Mr. F. H. Edwards remarked that he had read of experiments in this respect, and asked for enlightenment, if any of the members had been closely following the subject. Mr. Parsons had read that the scheme was worked by means of duplicate cables and connecting wires by means of which the current was supplied to the ground. The Chairman mentioned experiments which had been made in a greenhouse. The application of electricity to the roots had, besides hastening the growth of the plant, greatly increased the yield. He promised to look up further information to place before members at the next meeting. Mr. Ledger understood from what he had seen in print, that the ground could be supplied with the necessary electricity for a few pence per acre.

Pinnaroo, July 27.

PRESENT.—Messrs. B. L. Harfield (chair), A. W. Burman, F. G. Bonnin, J. Docking, H. E. Dibben, F. H. and P. J. Edwards, L. M. Ferguson, W. H. and W. A. Kelly, H. Ledger, C. Lee, J. Letherby, F. Laycock, M. McCabe, B. H. Nash, E. H. Parsons, H. I. Reed, J. Scales, P. H. Jones (Hon. Sec.), and one visitor.

MALLEE COUNTRY FARMING.—Mr. H. Ledger read the following paper:—"Since the Pinnaroo district has demonstrated its productiveness there has been an eagerness on the part of a good many people to secure a block of land and start on their own account as farmers, and it must be admitted, judging from the experience of last season, that a good many have not fully counted the cost, nor do they fully realise what capital is involved in starting a farm in new mallee country. It is not my intention, and the idea is farthest from my thoughts, that this paper should suppress any man's intention to go on the land. On the other hand, I think every man who is willing to give his whole time and energy to subduing this class of country should be encouraged and helped, as every acre properly cleared is a valuable asset to the country. There are, in my opinion, two very important questions one should consider—'Am I adapted for the life?' and 'Have I enough capital?' If both can be answered in the affirmative then success should naturally follow; but, if a man likes the town better than the farm, or if all the capital he has is in his muscles, he will not succeed. It is wonderful what a man can accomplish by hard work and good management, but the man who cannot rough it and put up with a few difficulties should not entertain the idea of mallee farming. As to the amount of money required I am here giving a few figures. I am taking a crop of 300 acres. One person can manage this, providing water and things in general are fairly handy. £20 for Government fees and preliminary expenses; £60 for rolling, and I should suggest getting someone on the spot to do this if possible; £180 for horses. Six young horses should be got together for the money. The majority of old horses are dear at any price. £40 for cultivator. I am of the opinion that a tine cultivator is the most suitable for a man starting. I do not in any way wish to say that the cultivator is better than the plough if time and expense are put out of the question. £40 for drill; £60 for seed; £30 for super; £80 for chaff for six horses for six months. I strongly advocate getting chaff from a clean district, as it is evident that the rubbish that is sometimes brought as chaff is giving a good deal of trouble already, and it should be everyone's endeavor to keep down pests in the shape of weeds. £100 for buildings, stable, and camp; £20 for a vehicle. A tip-dray is always handy on a farm, and a wagon that would suit for a year or so may be available. I am not in favor of spending elaborately when means are limited. £25 for fencing. This usually consists of one barbed wire and posts half a chain apart. £40 for rations, &c., making a total of £695. I have made no mention of harness; but rail expenses and contingencies may be safely put down at £100. With a 12-bush harvest, and wheat at 3s. 6d. per bushel, the return from 300 acres would be £630, a deficit of £65 on the expenditure, without any allowance being made for the cost of taking off the crop, &c." In discussing the subject, Mr. Nash suggested the purchasing of second-hand machines, which could often be procured at prices far below those quoted in the paper. In the winter months a farmer might well employ his time and team by doing road work and other such jobs, and so add to his earnings. Unless a farmer possessed sufficient capital to commence and work a farm in a thorough manner it was a wise step to let it on the share system. Mr. P. J. Edwards pointed out that the loss would not be so great as the figures indicated, for such items as horses, rolling, fencing, &c., were assets, and consequently would not appear among the debits in the following year's returns. Then again, the farmer might possibly have been able to cut sufficient hay and so do away with the purchase of horse feed. Mr. F. H. Edwards would not recommend the purchase of second-

hand implements. The mallee was by no means a poor man's country, and he thought £1,000 little enough to start farming in such districts as this. Many had been successful on less, but then they had been favored by good seasons. Mr. Bonnin was of the opinion that the writer had rather underestimated the costs. Mr. Ledger, in reply, drew attention to the fact that there were various other expenses which were items to be considered when one was hard pushed. He emphasised the necessity of always securing young stock.

Wilkawatt, June 27.

PRESENT.—Messrs. J. Ivett (chair), D. F. and D. Bowman, J. W., F. W., and G. A. Altus, T. and C. Sorrell, E. W. Brooker, A. V. Ivett, A. J. McAvaney, F. and B. Spackman, W. R. and M. Neville, F. W. and W. H. Gasmier, H. H. Pritchard, R. Sinclair, B. Tylor, P. Maher, P. Rigney, W. J. Tylor (Hon. Sec.), and four visitors.

RATE.—A cutting from a newspaper on this subject was read by Mr. A. V. Ivett. Members discussed at length the advantages of feeding rape to cows, and it was stated that if bran and rock salt were provided no taint would be noticeable in the milk.

FENCING.—Mr. D. Bowman, in a paper on this subject, said the best fencing posts for this district were made from sawn timber. Care should be taken that the holes for the wires were not too small. Wooden posts should be placed 18in. in the ground, with the strainers 2ft. 6in. in. Struts should be placed against the top of the strainers, as they would then better serve their purpose. For a boundary fence he would put in one wooden post and then four T-iron posts 10ft. apart. The top wire should be put up first and the other wires should be placed at reasonable distances apart, so that there would be no danger of the stock getting their heads through. In reply to a question, the writer of the paper said that a $\frac{1}{2}$ in. auger could be used for the posts and a $\frac{1}{4}$ in. auger for the strainer. Mr. Neville was of the opinion that it was better to put the struts near the bottom of the strainers, but the majority of members were of the opinion that this was not very secure.

Wilkawatt, June 29.

PRESENT.—Messrs. J. Ivett (chair), D. F. and D. Bowman, J. W. and F. W. Altus, C. and T. Sorrell, E. W. Brooker, A. V. Ivett, A. J. McAvaney, F. and B. Spackman, W. R. and M. Neville, F. W. and M. H. Gasmier, H. H. Pritchard, R. Sinclair, B. Taylor, P. Maher, J. W. Taylor (Hon. Sec.), and five visitors.

MALLEE SHOOTS ON GROWING CROPS.—The question as to whether cutting mallee shoots just before rain on a growing crop would be detrimental to the wheat was replied to by Mr. J. Ivett, who stated that if the shoots were large and the rain brought the tan out of them the growth of the plant would be affected. Mr. M. Neville thought shoots cut whilst rain was falling damaged the crops.

DRAKE.—Mr. M. Neville was experiencing trouble with drake coming up on fallow land which was just being drilled. Mr. J. Ivett advised putting sheep on to the land, and Mr. A. J. McAvaney thought the best plan would be to run the harrows over it immediately.

* STABLE MANURE ON GROWING CROPS.—In reply to a question as to whether any harmful effects were likely to follow the spreading of stable manure on growing crops, Mr. Sorrell stated that no harm would be done provided the ground was not dried too quickly by the sun afterwards.

POULTRY.—The following paper was read by Mr. A. J. McAvaney:—"It would be to the interest of farmers to keep a poultry yard on their farms, as with a little care a good profit can be made. I prefer keeping mixed breeds, White Leghorns being a good laying variety, and easily reared, should be in the majority. I would also keep a heavy breed for table purposes. In this district, where the water is plentiful, it is advisable to sow a small plot of lucerne, as this a splendid feed for fowls during the summer months. They are very fond of it, and it is better than other green feeds. All otherwise waste food can be utilised and converted into cash." A good discussion resulted. One member favored the keeping of a cross between White Leghorn and Dorkings. Members generally believed in the idea of growing lucerne for fowls, as it was preferable to crushed bone, &c.

TAKEALL.—Mr. J. Ivett read a paper on "Takeall and How to Control It," as follows:—"Takeall is one of the greatest pests with which the farmer has to deal. There are two practical ways of eradicating the disease, one is clean fallowing, and the other a suitable change of crop, such as oats or rape. The disease can be readily recognised, as portions

of the crop become blighted or withered: the green plants turning greyish-white, and in some cases being entirely destroyed. A distinguishing feature of the disease is that it occurs in patches of all shapes and sizes. On making an examination of the diseased plant it will invariably be found that the base of the stem has a brown or black discoloration. Takeall is found most frequently on old, continuously worked land; but it also appears on fallowed land and on new land fallowed and unfallowed. Careful and thorough methods will effectually stamp out the disease. It is recognised that it is a fungus which is reproduced from year to year by means of spores left in the ground from the previous crop. Whilst there are any spores in the soil the disease is likely to appear in the wheat crops growing in that soil. The only practical method of cleaning the land is to allow, and if possible to assist, the spores already in the soil to germinate, at the same time preventing the fungus from maturing and thus reproducing fresh spores. This can be done by killing it by starvation. As the fungus cannot obtain its food directly from the soil, but must obtain it by living upon wheat or certain other plants, it can be killed by preventing the growth of such plants. This, of course, necessitates a change from wheat-growing for a while, and it also means that the fallows must be kept free from plants on which the disease might thrive. It is known, for instance, that takeall will live on barley, barley grass, and spear grass, and probably on other plants, but it is also regarded as established that the fungus will not live upon oats or upon rape. The constant working of the soil brings to the surface fresh spores which germinate, and, in the absence of food, perish. The farmer who cannot afford to lose a year should certainly plant oats or rape. Even in this way the pest may prove a blessing in disguise, for it may serve to convince some that a continuous cropping with wheat may increase and spread the disease, while a change of crops will check it, and clean fallowing will most likely stamp it out altogether." In reply to a question, Mr. Ivett said that if takeall lived on drake it would kill it. Several members stated that where wheat had died through takeall drake still lived.

SOUTH AND HILLS DISTRICT.

Cherry Gardens, June 25.

(Average annual rainfall, 35·3in.)

PRESENT.—Messrs. S. W. Chapman (chair), T. Jacobs, J. Lewis, J. Tozer, C. Lewis, A. Broadbent, G. Hicks, H. Jacobs, H. Lewis, E. Broadbent, A. R. Stone, T. Jacobs, jun., J. Mildwater, S. H. Curnow (Hon. Sec.).

THE CULTIVATION AND WORKING OF HILL SOILS.—A paper on this subject was read by Mr. E. Broadbent, in which he discussed the most profitable means of working the soil in the Hills. In view of the limited size of the holdings it was essential that the very best use should be made of every available space. The man who was content to treat his soil in a haphazard manner could not expect to reap a good harvest. It was generally the practice for the landholder to devote the greater part of his time to the flats, and the true value of the hillsides was not recognised. To work any class of soil satisfactorily it was necessary to fallow early, and this applied to the hillsides. He would plough to a depth of 7in. or 8in. and leave the ground in the rough state until the end of the spring. Then the cultivator could be run over it, and the harrows could follow during the summer. This would leave a nice smooth surface and assist in conserving the moisture. The roller could be put over the ground at this stage with advantage. He believed that, tried over a number of years, the above system would be found profitable. When fallowing during a dry season the cultivator could be put over the soil, and a nice seedbed would be the result. Consequently the seed would germinate immediately and not remain under a clod for a week or so, as was frequently the case when other methods were adopted. Mr. T. Jacobs, in discussing the paper, said the chief difficulty in connection with the working of the hillsides was the loss of valuable soil through heavy rains washing it away. Mr. Stone agreed with the contentions of the paper writer, and thought that in the past the value of the gully soil had been overestimated. This dried up quickly in the summer, whereas the hillsides retained their moisture for a longer period. Mr. Curnow drew

attention to the fact that the retention of moisture was governed to a large extent by the presence of humus in the soil. Where there was plenty of humus the soil was not likely to dry up so quickly, as it could be reduced to a finer tilth. He recognised, however, that many of the flats were constituted principally of black clay. This of course cracked and liberated the moisture. Mr. Jacobs said this class of land should be treated with gypsum, lime, and salt.

Kanmantoo, June 29.

(Average annual rainfall, 17in.)

PRESENT.—Messrs. W. Downing (chair), H. E. and W. Shepherd, R. and S. Downing, R. T. Critchley, L. Wooley, W. Mills (Hon. Sec.), and one visitor.

FARM IMPLEMENTS.—The following paper was read by Mr. L. Wooley:—"Considering the high price of machinery, there is no better investment for a farmer than that of providing sufficient shelter to protect his machinery from the weather. It is not absolutely necessary that implements constructed of iron or steel should be under cover, because they can be painted occasionally to prevent them rusting. Every farm should be provided with a good supply of bolts, so that breakages can be promptly and properly attended to. If machinery has been travelling over rough roads the operator should tighten all nuts, and see that everything is in perfect working order before starting. The neglect to take these precautions will often result in a great deal of delay and expense. The seed drill requires considerable attention; and a good cover should be thrown over it at night. Before starting in the morning it is advisable to try the feeders, to see if they work freely, because, if sticky manure is used it will probably have become set during the interval, and the feeders will require cleaning. It is also necessary that a tarpaulin should be thrown over the binder to protect the canvas, while the belting of strippers and harvesters should receive similar attention. After the season's work is completed, all grease and dirt that has accumulated should be removed; a little kerosene may be used to facilitate the operation. This is also the proper time to overhaul and repair machinery for the coming season. Just after working a machine a person is better able to decide just what parts need adjusting than he would be after the machine had been put away for a while. This practice would also avoid any loss of time through inability to obtain parts of the machine quickly. The oiling of machinery is a very important matter, and the operator should not be neglectful in this respect. If he overlooks any of the oil cups it means that the machine is allowed to run dry, and this is the most frequent cause of breakages. It is advisable to use a little at a time and often, for if too much is applied at once there is not only a waste but a tendency for dust and dirt to accumulate, and this will gradually work into the bearings. Other points to be observed are—the oiling of all leather belting, the painting of woodwork, &c. Frequent painting of machinery can be avoided to a considerable extent if the covering mentioned herein has been provided, as the greater part of machinery required on the farm is only in actual use a few days or weeks in the year. Of course, vehicles should be painted every three or four years. The tying of wheels should be entrusted to capable tradesmen, because a good wheel can be easily spoiled through bad tying. The best materials for erecting sheds are iron and stone. Taking all things into consideration iron is less expensive, besides making very attractive outbuildings when properly finished."

Lyndoch, June 27.

(Average annual rainfall, 23in.)

PRESENT.—Messrs. A. Springbett (chair), J. Mitchell, H. Schrader, E. J. R. Woolcock, J. Woolcock, H. Klaube, H. Springbett, P. N. Burge, H. Kennedy, W. F. Haese, and J. S. Hammat (Hon. Sec.)

OIDIUM.—Mr. J. Woolcock read the following paper:—"Oidium is a mould that grows exclusively on the outer tissues of the vines, and attacks only the green organs of the plant, viz., young shoots, buds, leaves, tendrils, flowers, berries, and stalks. It appears first as a dirty white efflorescence, extending like a thin film, and possessing a characteristic mouldy smell. After the attacked wood has become ripe and hard, the imprints of oidium may be seen as dark-brown patches on the surface of the bark, which is not gnawed through as in the case of anthracnose or black spot. The wood is liable to dry up in winter, and should never be selected either for cuttings or as scions for grafting. Very often the

invasion occurs after blossoming, and in that case it mostly attacks the leaves and bunches. Should it appear early, and unless proper attention is paid in due time, it will cause the flowers to abort. The tender leaves are the first and the most seriously attacked, the disease showing preferably on the under surface. Its meshwork of microscopic shreds or filaments spreads around them, and they soon shrivel and dry up, while their full power as organs of evaporation and of assimilation of some of the constituents of the air is seriously impeded, and the must of grapes coming from affected vines is never so rich as in the case of well-matured and healthy grapes. It is the berry, however, that the fungus seems to most particularly cherish. They are either entirely or partially covered with a whitish greasy powder which at first can be rubbed off without leaving any trace, but which, after a few days, when the powdery mould has taken a greyish tint, leaves, when rubbed off, little black specks on the surface of the skin. The effect of the fungus on the skin is to tighten it and prevent it from stretching, so that the berries either dry up or burst open. The ripening does not progress satisfactorily, the berries assume a dull and sickly color after they have turned, and are none too good for making wine, as they have a mouldy taste. Oidium as a rule flourishes best in localities where the atmosphere is generally warm, moist, and muggy, while it is not so troublesome in a hot and dry climate. Again, some varieties of vines are more susceptible to the disease than others, and the vinegrower should watch in the spring and early summer for possible invasions. All vinegrowers are acquainted with oidium, and a great majority know that sulphur is the best remedy for the pest. A great many, however, may not be aware that there is a form under which sulphur is more active for that purpose, and also that the state of the weather and the time of day when the application is made have a direct influence upon the efficacy of the remedy. Atmospheric conditions have a considerable influence over the growth of oidium. A warm temperature favors its growth, but great heat, such as when the thermometer rises up to 95° Far., stops the progress of the fungus, which actually dies out when the temperature reaches 113° Far., though its debris, when the circumstances become favorable, soon cause a new invasion. It is often noticed, especially in warm districts, where the temperature close to the surface of the soil is very high owing to the radiation of heat, that the lower leaves, as well as the bunches that hang pretty low, are free from the disease, while on high trellises under similar circumstances, it is seen to blight the vine and wither the crop. Experiments conducted in all parts of the world have conclusively demonstrated the action of sulphur against oidium, and powdered sulphur, as well as flower of sulphur, is now used everywhere. It is not necessary, moreover, to bring the particles of sulphur into immediate contact with the spores and fungus threads to effect their destruction, as the fumes which this substance in a fine condition emits at elevated temperatures, and especially by exposure to the sun and heat, are the only active agents of destruction of the mould. Under the action of heat the sulphur is oxidised, and sulphurous acid is formed, which is an efficient insecticide and mould destroyer. That action, it has been noticed, is more pronounced when the sky is clear and without clouds than in a diffused light. In places where the temperature of the soil rises as high as 110° Far., spreading the sulphur on the ground under the vines is sufficient to accomplish the destruction of the fungus. Sulphuring, to be efficacious, must be used as a preventive. If the treatment is delayed until the formation of the fruits of the fungus it is not likely to do much good, for, although it may destroy the mycelial threads, the seeds of the fungus are too well protected within their hard coverings to be injured by the application. The best time for sulphuring is early in spring, when the shoots are 4 in. long; then again just about the time of blossoming, as however well the applications may have been made, it is almost certain that some of the terminal cells of the mycelial threads, swollen and filled with a transparent granular matter, will escape destruction. These, with spores brought from other vineyards, may bring a new infection in about three weeks time. At this period the blossoms may be rendered sterile by the threads of the oidium covering the newly-expanded flowers and causing them to abort. A third application should be made a few days before the turning of the berries. In wet seasons, or in a moist district, as many as five and sometimes six sulphurings may be necessary, and no hard and fast rule can be laid down for each application. The person in charge should use his judgment and sulphur more especially the varieties most subject to oidium until the pest has completely disappeared. There are many ways in which it can be applied, i.e., by a piece of branbag held by the four corners and shaken over the vines, a dredging box similar to a flour dredge, or a sulphur bellows. The bellows are most widely used, and most effective, as the operator can get at the underside of the foliage where the disease will appear first. Last season I saw some very bad cases of oidium on vines, and the owners did not know what the trouble was. It was then too late to apply the sulphur with a view of saving the fruit.

BERSEEM.—Mr. H. Springbett tabled a bundle of berseem which had grown to a height of 10in. This Branch had purchased and distributed during the last week in March, 1912, 2cwt. of seed of this clover and 12 persons had experimented with it. In nearly every case the result was a failure. The seed germinated very irregularly, and the greater proportion of the young plants died. Mr. Springbett had irrigated a piece of ground and then ploughed it. Thirty pounds of berseem was sown on April 4th on sandy soil. Lucerne planted alongside was making much better growth. Seventy-nine days from the time of sowing the plot stood 10in. high, and it had been watered twice since germination. The water used was from a well containing a percentage of magnesia that suited lucerne, but which was too strong for vegetables. Many foreign weeds were growing in the crop. Mr. Linke had sowed a few ounces of seed in his garden, which he irrigated with water from the Barossa reservoir. The height of the plants was from 13in. to 15in. and the crop appeared to be doing well. The Hon. Secretary drilled in 12lbs. of seed on April 11th, and also 8lbs. of lucerne and 1bush. of barley alongside. The soil was a loose loam, moist, but not irrigated. Of the berseem a few patches were from 2in. to 3in. high; 60 per cent. to 70 per cent. of the seed did not germinate until May 28th or 29th. The lucerne crop was uniform, of better color, and appeared to be doing better than the berseem. The barley had reached a height of from 15in. to 18in. It was generally remarked that owing to the climatic conditions of 1912 this fodder had not been a success in this district.

MacGillivray, July 23.

PRESENT.—Messrs. R. Wheaton (chair), H. Ayris, A. Burfitt, J. Matthews, A. Stirling, sen., A. Stirling, jun., H. J. Wiadrowski, and H. C. Williams (Hon. Sec.).

CARE OF HORSES.—Mr. Burfitt contributed a paper on this subject, in which he drew attention to the fact that the proper provision of feed and water was the essential point. He found that between 8lbs. and 9lbs. of good hay chaff with a little bran added was a very fair ration. Each horse should be well cleaned down at least once a day, and where the prevailing atmospheric conditions were cold it was necessary to rug the animals when they were in the stable. The arrangement of the digestive system of horses pointed to the necessity of small feeds being supplied often, and this also applied to water. Each animal should be provided with a well-fitting collar, and where sore shoulders were prevalent, blacklead and lard could be applied. The medium draught was the best animal for farm work, as it did not eat so much as the larger horses. Every farmer should keep a stock of common medicines on the farm in case of emergency. Discussing the subject Mr. Stirling, sen., said he would water horses immediately after working, even though they were hot. He watered his horses either before or after feeding. Prevention of sore shoulders was better than cure. It did not necessarily follow that big horses were big eaters. He favored horses with weight rather than medium sorts for team work. Mr. Ayris deprecated rugging. For sore shoulders he used a false collar, which he kept well oiled and smooth. Horses should have water whenever they chose to drink. Mr. Stirling, jun., considered bran to be three times the value of chaff for feed. Mr. Wiadrowski believed in grooming each horse regularly whilst in work. Unless an animal was in a lather, a cold drink would not injure it. The danger of colic attacking horses that were driven through cold water when they were hot was instanced by the Secretary. Other members disagreed that this could have been the cause. He believed in warm stables without pampering the horses. A horse comfortably stabled during cold weather thrived better on a given quantity of fodder than it otherwise would. The Chairman had noticed that at a time when sore shoulders were prevalent horses that had molasses fed to them were not troubled, presumably because they were thereby kept in better health. Every feed should be cleaned up before more was given. An opinion was expressed that colic was sometimes caused by a change to green feed after a course of dry ration.

Meadows, July 1.

(Average annual rainfall, 34½in.)

PRESENT.—Messrs. G. Ellis (chair), T. B. Brooks, J. Stone, A. L. Ellis, W. J. Stone, F. Nottage, H. A. Kleemann, S. Smith, W. H. Bertram (Hon. Sec.).

THE CITY MILK SUPPLY.—Mr. A. L. Ellis read the following paper:—"Dozens of persons who used to keep one or two cows in and around the city and supply several of their neighbors are now compelled to do away with their cows altogether, owing to the expense which would have to be incurred in connection with the Food and Drugs Act. Of course.

this causes a greater demand from the man who has the milk round. Within a very short time the city and suburbs will have to depend on the country for the supply of milk. There is no substitute yet discovered for milk, and the demand will continue to increase if our capital city takes the same rapid strides that it has during the last 20 years. During the past six months one of the largest milk retailers in Adelaide has been depending almost entirely on the country for his milk supply, visiting Woodside and Gumeracha districts daily and taking delivery at the farms. Of course, getting the milk to the city will have to be done by motor power, where there is no railway, otherwise it will not be profitable owing to the time involved. In Victoria there is a special milk train for the Melbourne supply run from the Gippsland districts. In the near future the milk producers will not have to go to the factory, and there will be no separators to attend to. According to the price the retailer gets for his milk, 2½d. a pint (nearly as much as the producer gets for a gallon now), he can well afford to give 6d. or 8d. a gallon to the producer for his milk if the present rates continue. To those who go in for milk production on a large scale and with an up-to-date plant, this will be a good return. Unless a cow will bring in more than £12 or £13 a year she is not worth keeping. It costs as much to keep a bad cow as it does a good one. To keep cows in good condition they must have good feed and plenty of lucerne, mangolds, and ensilage for winter feed. People make a great mistake by depending too much on what nature provides in the spring time. Good stalls and sheds are essential. With these there is no feed wasted, and every cow has what feed is given to her. A cow will comfortably consume 100lbs. to 120lbs. of grass daily, so it is little wonder that there are such a lot of poor cattle in the country when one looks around to see where they have to find their food. The milk industry will encourage the keeping of heavy milkers rather than the rich creamers, because it is quantity that will tell. The milking Shorthorn strain crossed with Jersey and Ayrshire breeds should make a good milking herd. The southern districts will play a prominent part in supplying the city with milk. We have the country, and it must be made more productive than at present, and cows will be the best means of doing this." In the discussion that followed, the Chairman considered it would be more profitable to sell the milk right out at 6d. or 8d. a gallon than retain the skim milk from the separator or factory for feeding the pigs. The Hon. Secretary contended that it was the labor problem—holidays, Saturday afternoons, and Sunday work—that hampered the dairying industry at the present time, and unless the owner of a small dairy farm was prepared to do most of the work himself he would not be able to make it a success. Mr. Jacobs considered that the labor problem would work itself right in time, and that if the industry would not pay at the present ruling rate of wages and hours, a person would not keep any more cows than he and his family could attend to.

Morphett Vale, July 16.

(Average annual rainfall, 22½ in.)

PRESENT.—Messrs. A. C. Pocock (chair), L. F. Christie, sen., F. Rosenberg, T. Higgins, A. Anderson, H. V. Sprigg, W. Goldsmith, H. O'Sullivan, E. Perry, L. R. Christie, and E. E. Hunt (Hon. Sec.).

EARLY OR LATE SEEDING.—Mr. E. Perry read the following paper on this subject :—
 "On the small farms in the south, where most of the land cropped is fallow, a great many of the farmers sow far too early. In my opinion fallowed land should not be sown until at least 10 days or a fortnight after a good rain—an inch at least—as by then the weeds will have started and can be killed before sowing. Far stronger and healthier plants than that sown under dry conditions, which will produce cleaner and heavier hay, will be grown. This will always sell, even when hay is plentiful. By sowing before the rain, unless the land is free from weeds (which is very uncommon about here), one is certain to have weedy hay, as there always seems enough moisture for weeds to grow. In fact, I have seen stuff (I cannot call it hay) cut at the local chaff mill, the seed for which was sown before the rain, that was not fit to give to horses that were working hard. Another reason for later sowing is that black rust seldom badly attacks crops that have been sown under favorable conditions. If the rains are very late, like the present season, and it is getting late for a good growth of hay, it would pay the farmer to even change his seed and sow English or Cape barley and peas, which would pay far better than a poor crop of hay, especially now labor is so dear. Further, he would not be carrying all his eggs in the one basket. If the south is to keep its good name as a producer of the best quality hay the farmers will have to discontinue seeding in the middle of summer and patiently wait for

the season to break. The anxiety they have had lately will make them more cautious in the future, as dearly-bought experience is always best." Members discussed the paper at length. It was a difficult matter to determine when to sow in the case of a season like the present. Where late sowing was practised it was necessary that the ground should be carefully prepared.

Mount Barker. June 27.

(Average annual rainfall, 30·96in.)

PRESENT.—Messrs. H. N. Bell (chair), J. B. Paech, J. Brinkley, Jas. Cleggett, R. Hollamby, R. H. Grimes, S. J. Bishop, J. E. Smith, F. Simper, J. Thomas, A. Ferguson, J. Woolley, D. Wollaston, C. G. Braendler, E. Schmidtke, J. Hender, P. Davis, H. Jones, Bert Pope, J. Pope, A. C. Daw, A. P. Herbertson, D. L. G. Monfries (Hon. Sec.), and one visitor.

THE ONION.—Mr. F. Simper read the following paper:—"The onion is one of the oldest vegetables known. It is gaining favor year by year, therefore, it is necessary to increase the production to meet the demand. With a certain amount of knowledge and labor there are times when fair profits can be made by growing onions. In a district such as ours, where many of the holdings are small and the land expensive it is necessary to combine agriculture with gardening by growing root crops. From the outset, I wish it to be strictly understood that these remarks on onion culture are intended only for this district or one of similar soil and climate. Should I describe the best methods for Mount Gambier and parts of Victoria, where the soil and climate are so suited for onion-growing over large areas with less expense than here, I am afraid that many would be misled. Onions can be profitably grown in this locality, and harvested at a time when the markets are bare of a good export variety, if sufficient care is taken to select patches of soil that are suitable for raising heavy crops of good quality. With a fair summer, onions from this neighborhood can be harvested in February or before the bulk of the Gambiers and Victorians are ready. The soil most suited for this plant is a loose, deep, dark-colored loam, which must be fairly well drained. Onions will grow almost anywhere in this district; but if top prices are desired they must be of quality. The results of onion-culture on unsuitable land are too well known and far too risky to be recommended. If possible, select a patch of land that is open, giving all trees, hedges, &c., a fairly wide berth; and should it be at the foot of a hill, see that it is kept well drained in the winter; and also note that the ground must be kept free from weeds. Give the land a good dressing of yard manure at the end of the summer, or as soon as the former crop, whatever it may be, is taken off. After the early rain, plough as deeply as possible, then harrow it well. If very lumpy, put a soil grinder or roller over it; it can then be left until planting time, when, to improve the crop, an application of bone-super, at the rate of from 3cwt. to 5cwt. per acre should be applied. Onions have grown well on the same land several years following with the aid of manures; but a change of crop is necessary to obtain the best results. I would recommend late garden peas or potatoes for a change. There are many varieties of onions to choose from. I have found the Brown Globe most suitable here, as it comes to maturity between the early sorts, which will not keep long, and the late kinds that are rather delicate for our climate. Select the best bulbs from the last crop, or the best that can be purchased, true to name. If they are cross-bred, make sure that it has not been with an early sort, or a great deal of trouble will be experienced at harvest time. About June, plant these bulbs in rows, leaving a space of about 3ft. between every two rows, there will then be little trouble in gathering the seed heads. Promptness is required in gathering the seed when ready, as if left to get over-ripe much may be lost in handling. The heads should be cut off when about one-half of the seed is showing, and placed into large calico bags, so that it may be spread out thinly in the sun. When dry thresh it out and put it through the winnow. Take note that the onion seed loses its vitality very quickly, and should not be sown after two years old. After ploughing or digging a piece of loose dark soil, burn leaves and bark of trees on top of same, so that the ashes can be raked in before sowing the seed. This burning will force the growth of the plants, and will also help to prevent weeds from growing. Sow the seed in April in drills about an inch deep. If water is laid on, set the sprinklers going, and the young plants will show up in about three weeks. However, there will usually be sufficient rain to start the seed. Keep the seedbed well hoed, and by about the month of September, or when the plants are about 6in. high, transplant them in rows 7in. apart, putting the plants 4in. apart. Three rows may be set on two plough furrows 10½in. wide. When the planting is done after the plough, a line will not

be required, and much of the stooping will be obviated by walking along the open furrow whilst planting. Do not pull the plants when wet. Trim their tops and roots a little so that they may be the easier handled. The former leaves usually die off; but after a shower of rain they will take fresh root, and the hoe will need to be kept going to keep down weeds and the top soil loose. Some growers do not practise transplanting, and prefer to either drill in the seed or sow it broadcast at the end of winter, and when the plants are about 3in. high, thin out for a crop. The former plan, although the work of planting takes much time, is the surer and better one in this district. A good crop of onions should not be made up with a lot of 'stiff necks.' Good seed, with thorough cultivation on suitable land, will produce even-sized, solid bulbs. When the tops have fallen over they should be pulled and placed in rows, taking care to cover the bulbs with the tops to prevent the sun from scorching them. When dry, the tops and roots may be pulled or cut off, and the onions graded and bagged ready for market. The gunnybag has been used in the past, but the present-sized cornsack now in use is suitable. Use only new bags for export, and brand the bags well. In dry seasons the crop may be doubled by irrigation, the use of sprinklers being the best method. Diseases of this plant here are almost unknown; and, unlike potatoes, the onion is not hurt by the severe frosts. The chief trouble is with the lucerne flea, which attacks the young plants in the seedbed. A remedy for this is a spray of strong tobacco-water. Slugs also decrease the crop in wet seasons. Dusting with lime is recommended; but the hoe will help to eradicate the pest. Onion-growers, who do not make big profits, will not be able to say they have had no work. In conclusion, I would like to say it is necessary for producers to co-operate more in disposing of their goods, not with the idea of skinning the consumer, or even the middle man, but to find other markets that are wanting. Although Australia has been abundantly supplied with onions at times, on other occasions it has been necessary to import from New Zealand, Italy, and South America; therefore, when our markets are overstocked we should try South Africa and other countries." A number of questions were replied to by the paper-writer. The difficulty with broadcasting the seed was that if it were sown early it was liable to rot, and if it were sown later the crop would be ready for market when the outputs of Mount Gambier and Victoria were selling. Bone super. was a better manure for onions than bone dust. The most likely cause of the crop running to seed was too early planting, the seed being put in too deep, together with unfavorable climatic conditions. The cost of putting in and taking off the crop was approximately £25 to £30 per acre, and with favorable circumstances a yield of from 10 tons to 20 tons per acre should be secured. There should be no difficulty in keeping onions for one month. The practice of cutting the tops off was better than rubbing; but care should be taken that the cut was not made too close to the bulb, as the top kept it from bruising.

Narrung, June 29.

PRESENT.—Messrs. Thacker (chair), Hackett, Goode, Critchley, L. C. and L. H. Mann, J. W. and S. McNicol, Sullivan, Bolger, S. E. Morgan (Hon. Sec.), and two visitors.

SAND IN HORSES.—Mr. Bottrill initiated a discussion on this subject by reading several extracts dealing with treatment of horses suffering from sand. Mr. Hackett believed that some of the drastic measures taken were worse than the complaint itself. In some cases where oil was given it settled on the sand in the stomach and formed a hard layer, and no feed or medicine given the animal had any effect. Mr. J. W. McNicol had cured one of his animals by giving it a strong dose of coffee made with milk with a little carbonate of soda added, and then rolling the horse. Members generally thought that the best cure was to place the animal on its back and gently work the stomach. Mr. Bottrill drew attention to the inhuman treatment some stockowners meted out to their worn-out horses. He contended that when a horse became too old to work in the team it was better to shoot it than to sell it. However, horseowners should make provision for the declining years of their horses.

Port Elliot.

(Average annual rainfall, 20½in.)

PRESENT.—Messrs. H. B. Welch (chair), J. Brown, J. Barton, J. F. Vince, H. Green, W. E. Hargreaves (Hon. Sec.).

BUSH FIRES.—It was decided that the Port Elliot and Encounter Bay District Councils should be approached with the request that special constables should be appointed for

the purpose of seeing that the provisions of the Bush Fires Act were carried out. It was thought that, if convictions were secured for negligence in lighting fires, this would go a considerable way toward minimising the number of bush fires experienced in the district.

GYPNUM AND LIME.—Members were of the opinion that it would pay to make applications of gypsum and lime to orchard lands as, in addition to the manurial value, they would assist in keeping the soil open.

Port Elliot, July 20.

(Average annual rainfall, 20½ in.)

PRESENT.—Messrs. H. B. Welch (chair), J. McLeod, J. Brown, J. F. Vince, H. Green, H. Welch, W. E. Hargreaves (Hon. Sec.), and Mr. W. Eastwood, of Northfield Branch.

SALT AND GUANO AS MANURE.—A discussion on this subject was initiated by Mr. McLeod, who had used 1 cwt. of salt and 1 cwt. of guano to the acre. Where these two had been put on together he had been greatly troubled with sorrel, and for three years the sorrel was thicker than the crop. Where, however, he had only used guano he had secured a good crop of wheat and oats. Mr. Vince made a practice of using salt for vegetable growing. He had spread it with a shovel, and the results had been good. Mr. J. Brown had used about 5 cwt. of gypsum to the acre and had secured good crops of mangolds from the salt patches. Mr. H. B. Welch had spread farmyard manure and straw litter where there were salt patches, and in wet seasons good crops of wheat and oats were secured. It was pointed out that Mr. Grasby, of Balhannah, had used lime as a dressing for land on which to grow peas, with the result that the crop on the lime land was four or five times as heavy as the crop on the plot where 2 cwt. of bone super. per acre had been applied.

DRY BIBLE AND SAND.—Mr. W. Eastwood reported that he had used 12 packets of Epsom salts together with a little carbonate of soda as a remedy for dry bible, with good results. For sand in horses the Hon. Secretary had used 1 lb. of honey mixed with half a bottle of yeast, and the results were satisfactory. He tabled 36 small bones, of from 1 in. to 5 in. in length, which he had taken from the first stomach of a cow that had died after being bad for about 36 hours.

PHALARIS COMMUTATA.—The Hon. Secretary tabled a sheaf of this grass, being nearly 6 ft. in height. This was the third cut during the year, and it had been grown in stringybark country. Stock were very fond of it, and when chaffed it made excellent fodder for horses and cows.

Strathalbyn, June 28.

(Average annual rainfall, 19½ in.)

PRESENT.—Messrs. T. Collett (chair), P. Cockburn, J. Springbett, W. Watt, J. R. Rankine (Hon. Sec.).

COWS.—An interesting discussion took place as to the profitability of keeping cows. Mr. Watt strongly contended that a good return was secured from these animals, but attention was drawn to the allowance that had to be made for feed, which considerably decreased the profit.

PEAS.—The relative advantages of harvesting and feeding off peas was discussed. Mr. Watt thought it advisable to turn pigs on to the crop, as it would cost 2s. per bushel to harvest, whereas, when the pigs were fed on the peas a handsome profit would be realised. A consignment of 20 pigs that he had sold as fats had been fed on nothing but peas, from the stack in the winter and in the field in the summer, when the crop was ripe. The want of a pea-thresher that could handle 200 or more bags daily was greatly felt. A suitable machine would considerably decrease the cost of harvesting.

Uraidla and Summertown, July 1.

(Average annual rainfall, 42½ in.)

PRESENT.—Messrs. E. Hart (chair), W. H. Curtis, S. and E. Hawke, J. Rowe, A. Moulds, W. Kessell, H. F. Johnson, T. H. Collins, W. Squires, H. Shueard, G. Prentice (Hon. Sec.), and one visitor.

APPLE-GROWING.—The following paper was read by Mr. E. Hawke:—"In starting an orchard it is necessary to prepare the land well. All land on which apples are to be planted should be broken to a depth of at least 18in., either by subsoiling with the plough or grubbing. This gives the roots of the trees a chance to strike well down. Nearly all our land in these hills would grow excellent apples if so treated. The next point necessary is to make a good selection of varieties. To be successful you must find out which sorts are suited to the particular class of soil. Different varieties very often require different soil. Some do well in low ground. The Jonathan, for instance, should be planted in good land where it is not too dry, otherwise the fruit will be small. If the London Pippin is planted too low it will not develop into that good yellow color which is so necessary for the sale of this variety. About the best kinds to plant are—Early, Williams' Favorite, Early and Late Astrachan, Quarrenden (on a small scale) and Gravenstein; mid-season, Emperor Alexander, Worcester Pearmain, American Mother, Maiden's Blush, Jonathan; late, Rome Beauty, London Pippin, Cleopatra (which if you are prepared to supply with plenty of Bordeaux mixture is best of all) and perhaps Rokewood, though I cannot recommend it unless for its great keeping qualities. I am convinced that we cannot grow good apples without pruning them severely. I find it best to take the tops right off and thin them well, keeping the centre well open. Keep them under by cultivating all the young wood from the top right back. By so doing you will cause the tree to spur lower down. A low tree is better than a high one, as it is much easier to spray, and gathering the crop is much more easily carried out. The most important spraying to my mind is the first one in the spring. On this very often hangs the success or failure of the season. Spray with Bordeaux mixture as soon as the bloom begins to show; get the spray on the stem of the apple. The *fusicladium* starts on the stem first and works up to the fruit: by putting the spray on early it will prevent this. As soon as the apple has set, spray with arsenate of lead. Through the season give about three sprayings and the codlin moth will not be troublesome. I had a large Stone Pippin tree which did not bear for years. Last year I grubbed it back to a depth of fully 18in. and pulled off a lot of blighted lumps of roots, and pruned hard. The result was a crop of 9bush. of first class apples. When planting young trees too many of the same variety should not be put together, but sorts which bloom at about the same time should be close to one another on account of the advantages secured from cross-fertilization." In discussing the subject, Mr. H. Shucard expressed the opinion that Cleopatra and Stone Pippin were the best varieties to grow, provided they were well pruned and sprayed. Mr. Squires would plant young trees in well-cultivated soil, but not too deeply, and would spray them with Bordeaux mixture mixed in the proportion of one to eight. Mr. Kessell favored Stone Pippin for cooking purposes, and Mr. Moulds believed that in the majority of cases apples for export were picked and packed before they were ready. Gravenstein was a good export variety.

SOUTH-EAST DISTRICT.

Kybybolite, July 20.

(Average annual rainfall, 22in.)

PRESENT.—Messrs. Bradley (chair), Duffield, Schinkel, Koth, Lacey, Smith, Alcock, Colebatch, A. R. Scholz, C. H. Scholz, D. G. Scott (Hon. Sec.).

CARE AND FEEDING OF HORSES.—In a short paper under this heading Mr. Duffield said that when ploughing was commenced care should be taken not to work the horses for too long a period without a spell. This would go a long way toward obviating sore shoulders. When ploughing, it was bad policy to rush the team. The best ration was made up of wheaten and oaten hay mixed, with an allowance of long hay given at night. The latter should not be given in sheaves, as this resulted in a considerable waste. Rugging should be always carried out, whether the horses were stabled at night or not. The writer of the paper had made a practice of rugging his horses for the last eight years, and he was a firm believer in it. When turning horses out, however, it was not advisable to leave the rugs on them as when rolling they would tear them.

Millicent, July 20.

(Average annual rainfall, 28½ in.)

PRESENT.—Messrs. H. F. L. Holzgreffe (chair). J. Bowering, G. Searle, W. Downs, and H. Day (Hon. Sec.).

MELILOTUS.—A discussion took place on the value of melilotus as a food for stock. Mr. Holzgreffe said this plant was highly valued in the Wimmera district of Victoria. Mr. Searle remarked that it had become a nuisance to him, but members generally agreed that it was a useful fodder.

DRILLING.—Mention was made of the slovenly methods of drilling which, unfortunately, were noticeable in some paddocks. Late ploughing and a rough harrowing was not good farming, and when the drill was run in a wavy fashion, or perhaps in a half circle over the weedy land, the result was an eyesore to the practical farmer and a loss to the owner.

Mount Gambler, July 13.

(Average annual rainfall, 31½ in.)

PRESENT.—Messrs. A. J. Wedd J. Botterill, J. C. Ruwoldt. E. F. Schlegel, C. T. Major, H. Kennedy, G. Keegan, R. Smith, H. Wheeler, H. Pick, A. Sassanowsky, H. Buck, J. A. Engelbrecht, P. Pritchard, F. Holloway, G. F. Holloway, and D. Collins (Hon. Sec.).

BERSEEM.—The following report on this clover was supplied by Mr. Engelbrecht :—
 “ Following the directions of Professor Perkins, I planted 30lbs. of seed to the acre immediately on its arrival from Adelaide, which was late in March. The land selected was rich volcanic soil, and what I considered the best on the farm. A crop of early potatoes had just been lifted from it. After ploughing to a depth of 5in. it was harrowed down to a fine tilth. Owing to the fineness of the seed, considerable difficulty was experienced in regulating the broadcasting machine, with the result that the ground had to be covered three times to distribute the seed evenly. It was then rolled with a light field roller. An acre and a half adjoining was drilled with a mixture of rye and Cape barley at the rate of 3bush. to the acre. Heavy rain fell early in April, and the berseem germinated well ; but from that out it had a very unhealthy appearance. As time went on the growth was slow, and when about an inch high it looked very delicate and had a slight tinge of red on the upper leaves. At this stage a number of self-sown potatoes made their appearance and grew to the height of about 6in., when they were attacked by a heavy frost, which cut them down completely and killed them outright. The berseem did not seem to be affected ; at any rate no change was noticeable. Cape weed, however, now appeared, and very soon challenged the berseem, which now seemed to shoot up with thin, lanky stems. The Cape weed soon had possession, and at the time of writing (July) was a foot high in places. In the meantime the rye and barley had made splendid progress. Mowing was begun early in June, and since then 20 milch cows and two horses have been fed with as much as they could eat from it, and there is still sufficient to last another fortnight. If the berseem were acclimatised and planted earlier in the year the result might have been different ; but I question whether under any conditions it would grow half as much fodder as the mixture above referred to.”

POINTS FOR PRODUCERS.

Agricultural Bureau Conference at Meadows.

The Annual Conference of Hills Branches of the Agricultural Bureau is to be held at Meadows South on Monday, October 21st, commencing at 10-30 a.m. The arrangements are in the hands of the local Branch, and the agenda paper will include some practical addresses by agriculturists and horticulturists in relation to the producing industries of the district. All interested are invited to attend.

Horse Improvement in Britain.

Replying to some remarks in the House of Commons on the Government's work of horse improvement, Mr. Runciman, President of the British Board of Agriculture, said that the board had in view not only the breeding, but the retention in the country, of the best kind of light horses for sporting, agricultural, and military purposes. The amount of money spent by the board this year on premiums and super-premiums for stallions was larger than ever before. He regarded the purchase of stallions by the board as only an alternative to be resorted to if the premium system failed. Last year the board spent £8,700 on premiums and on the amount paid by the board for service fees. That enabled something like 50 stallions to be used throughout the season. Among other things, the board was also helping the cause of light horse-breeding by assisting country committees to purchase some 200 half-bred mares of substance. Last year only 312 stallions were registered by the board, but by May 31st last over 700 were registered as sound and fit, and they were travelling the road.

Californian Fruit Production.

Particulars of the 1909 census relating to the production of fruits and nuts in the United States which have recently been published show conclusively the ever-increasing pre-eminence of California. The total value of the crops mentioned in the State for the year 1909 was over £10,000,000. Of the nut crop which, in the United States, amounted to £459,400, California produced approximately £449,350 worth of English walnuts alone. Of semi-tropical fruits, including oranges, lemons, olives, figs, and pomeloes, California produced a crop valued at £3,350,000.

Health and the Farm.

The following passage is taken from a paper on "Farm Life Inducements for Young Men," read at a meeting of the Kansas State Board of Agriculture : — "Health is a heritage of the farm. It is the embodiment of energy, stamina, initiative, and virility. In large cities laborers who thrive by right of muscle alone are employed largely in the grinding work of mechanics, where they must toil under more or less unwholesome conditions, which tend to rapidly deplete their physical strength, and sooner or later leaves them without position and with little left for their declining years. The city man, intellectually occupied, too frequently becomes pale, nervous, and worn in the fetid atmosphere of confinement. The city is a marsh light. It lures with glitter and gaiety, its theatres and clubs, its kaleidoscopic activities ; but eventually the dweller of the city pays dearly for the privilege of congestion and contamination. It is when the experienced eye, looking below the surface of things, views the tragedies of the city, that he longs for that indefinable, soothing, and consoling something which we term Nature, and yearns for that bodily fitness which is found at its best in the open life and pure air of the country. Yes, health is one of the strongest inducements the farm offers ; and this is true now more than at any time in the past, because in addition to natural favorable environments, the farmer of to-day is guided more by scientific methods of living, systematically and conscientiously executed, which operate as surely as cause and effect for his physical betterment."

Bitter Pit.

Professor D. McAlpine has presented to the Federal Government his first progress report on the subject of bitter pit. No conclusions have been drawn, as the inquiry so far has been in the nature of clearing the way for definite investigation later. A lot of laborious initial work has been done, and it is evident that Mr. McAlpine is dealing with this intricate subject in a practical and scientific manner. The apples which, as regards their susceptibility to bitter pit, are classified by Mr. McAlpine as "very bad to bad," are Anne Elizabeth, Buncombe, Cleopatra, Cox's Orange, Lord Wolseley, Magg's Seedling, Northern Spy, Prince Bismarck, Ribston Pippin, and Shockley. The "medium" are Delicious, Duchess of Oldenberg, Esopus Spitzenberg, Hoover, Nickajack, Shepherd's Perfection, Prince Alfred, Rokewood, Sturmer. The "slight to very slight" are Ben Davis, Dumelow's Seedling, Five Crown, Gravenstein, Jonathan, Murroe's Favorite, Pomme de Nieve, Reinnette du Canada, Rome Beauty, Rymer, Scarlet Nonpareil, Statesman, Stone Pippin, and Winter Majetin. Mr. McAlpine has been successful in obtaining many excellent photographs, which show the effects of bitter pit in its various forms. —*The Fruit World.*

Agriculture in Great Britain.

A report from the Board of Agriculture on the total output of agricultural land in Great Britain, in connection with the Census of Production Act of 1906, has been published. The figures relate to the year 1908. In summarising the figures it is explained that the "total output" is represented by the value of the products sold off farms, partly in crops as grown, and partly in animals and their products. Thus, the total value of the farm crops of Great Britain in 1908, at market prices, is put at £125,000,000, of which the sum of £46,600,000 represents the portion actually sold; the remainder, except for a comparatively small proportion consumed by farmers' households, went to feed the stock and to maintain the fertility of the land. The chief headings are those of farm crops actually sold, £46,600,000; fruit, flowers, and timber, £5,200,000; animals, £61,400,000; wool, £2,600,000; dairy produce, £30,000,000; poultry, £5,000,000; total, £150,800,000. Reckoned on the 47,795,323 acres covered by the total value of the produce, the output amounts to about £3 3s. 1d. per acre; but the range is very wide, that of woods, for example, being only about 6s. per acre, and that of 13,000,000 acres of rough grazings only 10s. to 12s. per acre. On the 32,000,000 acres of "cultivated land," of which nearly 17,500,000 acres are in grass, the grass output is estimated to average nearly £4 10s. per acre. Attention is drawn to the fact that the returns on which the estimates are based do not cover holdings of less than one acre, and that, therefore, they cannot be regarded as complete, especially in connection with pigs, poultry, and minor crops, while the great but unknown amount of produce grown under glass is not included. Further, it is remarked that the agricultural produce of a single year is not to be taken as an average. In addition, it may be pointed out that, although the schedules of inquiry were sent to all occupiers of an acre of land or more, the returns for certain classes of produce were only 28 per cent. to 37 per cent., upon which proportions estimates for the whole were based. The estimates for the principal crops, however, were based on the ordinary agricultural statistics and the official price averages.

Development of Irrigation in the United States.

According to the last national census, the total acreage under irrigation in the arid and semi-arid States is given as 13,739,499 acres. This is an increase of 82.5 per cent. in the last decade, and 278.3 per cent. in the last two decades. The total area of irrigable land in the United States included in present projects and yet to be irrigated, comprises 31,112,110 acres. This vast area does not contain the total irrigable land; it is probably about half of what will ultimately be irrigated in the arid region. Professor Potrier, an authority on irrigation matters, estimates that the area susceptible

of successful irrigation is about 50,000,000 acres of land in the arid region, this area being all that the visible water supply in the territory designated will cover to advantage. When the ultimate development in irrigation in the West is reached, say in about 20 years, the irrigated section will support a population several times greater than at present, and land values will be proportionately higher. The extension of irrigation will result in a better conservation of our water supply, also in a more economical and effective use of irrigation water than is now practised. As land values increase, improved methods of irrigation will be adopted, and water will be made to perform a much greater duty than at present.—*The Irrigation Age*.

Farmers and the House of Commons.

Writing to an English farmers' club recently, Mr. Jesse Collings, M.P., asserted that in the House of Commons, while there are a number of bankers, lawyers, railway directors, shipowners, and other commercial men, there are only three farmers. The President of the Board of Agriculture is a shipowner, and the only farmer in the Government is a Lord of the Admiralty. He urged the farmers to unite to alter this state of things.

To Clean Testing Glassware.

In testing milk it is important that the pipettes and testing flasks should be kept as clean as possible. Unless the flasks are immediately emptied and thoroughly washed after testing, a film or coating of fat adheres to the inside of the glass which may appreciably increase future readings. In emptying the flasks after completing the tests; shake them up and down in order to remove the calcium sulphate deposited on the bottom of the flask during testing. Then add to each flask about 15 c.c. of the following mixture:—1oz. of potassium bichromate dissolved in 1 pint of sulph. acid. Shake well, empty this mixture and use a test flask brush and run it up and down the neck of the flask. Have the flasks in soapy water, and finally rinse in warm water, and allow the glassware to drain.

Irrigation by Sprinkling.

Irrigation by sprinkling (says the *Irrigation Age*) is being tried in California, and is meeting with favor, the only drawback being the cost of installation. It is said that by turning on the spray during a cold night the air can be kept above the freezing point.

Farmwomen's Clubs.

A movement which has made great progress in the United States is the formation of farmwomen's clubs in the country districts. These have assumed various forms, but their efforts are specially directed to three principal objects, viz., (a) the artificial creation among the women of rural districts of those social relations which, whether owing to recent immigration or to the long distances between the farmhouses, could not otherwise arise among them; (b) the variation of the monotony of domestic occupations by some kind of recreation, the want of which leads many country women to prefer city life; (c) the enrichment of the minds of the women by a reciprocal exchange of useful information and knowledge.

New York Farmers' Institutes.

The record of New York farmers' institutes during the season of 1911 and 1912 shows that 358 meetings were held throughout the State. The total number of sessions was 1,261. Altogether more than 131,000 people attended these meetings. In addition to the regular institutes and institute schools, of which latter seven were distributed at widely separated points in the State, the institute lecturers addressed 12,600 pupils in the rural districts. They also assisted at conferences of teachers in charge of representatives of the State Educational Department. At these sessions more than 5,300 teachers were present. Approximately 180 lecturers addressed the various meetings, and every phrase of New York State agriculture was covered. Under the direction of the Commissioner of Agriculture, the farmers' institute work is being supplemented by the visits of experts to farms where special problems arise and where farmers desire the advice of experienced agriculturists.

South Australian Grown Tobacco.

For the past 10 or 12 years Mr. J. Selth has been experimenting in the growing of tobacco in the grounds attached to his residence at New Parkside. Up to the present Mr. Selth has confined his attention to cigar varieties, and he claims that he has now passed the experimental stage, and has demonstrated that with proper treatment plants producing good saleable tobacco can be successfully grown in the locality mentioned. Next year Mr. Selth intends to experiment with the growing of pipe tobacco, a number of varieties of which have been forwarded to him by Mr. G. Ware, who obtained them from the experimental station in Ireland. Recently the Secretary of the Advisory Board of Agriculture (Mr. G. G. Nicholls) forwarded to the Director of Agriculture in Victoria for testing and analysis two leaves of Sumatra

tobacco which had been grown by Mr. J. Jarvis, of Walkerville, the plants having been supplied by Mr. Selth. Subsequently Mr. Nicholls stated that the samples had been thoroughly examined by the Victorian Tobacco Expert, who had reported as follows :—" The two leaves forwarded are a really nice sample of cigar leaf, being fine in texture, of a good color, and with not too heavy a vein and rib. The tobacco has not been properly fermented, and until this process is completed it is not likely to make a good smoking article with a nice flavor. I have, however, tested it, and found that it smokes fairly well, and burns a better ash than could be expected in the circumstances. I am convinced that if this tobacco were properly treated it would make a very saleable article, being suited for bunch, wrapper, or filler purposes. From the size of the leaf I would estimate a crop of about 600lbs. to 700lbs. weight of cured tobacco to the acre. If the sample forwarded is indicative of the whole crop its market value would be, say, from 10d. to 1s. a pound." It should be explained that the leaves were merely dried, placed between strips of cardboard, and forwarded in that state to Victoria. No attempt was made to ferment them in the ordinary way.

Irrigation in California.

During the last 10 years the number of irrigated farms in California has increased from 35,675 to 39,352, while the acreage irrigated has increased during the same period from 1,446,114 to 2,664,104. The length of all irrigation ditches in the State is 21,129 miles, which have been built at a cost of \$72,445,669.

Production of Grapes in United States.

The last census shows that in 1909 there were produced in the United States 2,570,936,310lbs. of grapes, having a total value of \$22,025,060. The production at that time was almost double what it was 10 years previously, when a crop of 1,300,751,066lbs. was gathered. The returns of the 1900 census secured no information as to the value of the grapes.

INQUIRY DEPARTMENT.

Any questions relating to methods of agriculture, horticulture, viticulture, dairying, &c., diseases of stock and poultry, insect and fungoid pests, the export of produce, and similar subjects, will be referred to the Government experts, and replies will be published in these pages for the benefit of producers generally. The name and address of the inquirer must accompany each question. Inquiries received from the question-boxes established by Branches of the Agricultural Bureau will be similarly dealt with. All correspondence should be addressed to "The Editor, *The Journal of Agriculture*, Adelaide."

CATERPILLARS BORING INTO PEACH TREES.

The Waikerie Branch of the Agricultural Bureau forwarded a number of grubs which were found under large lumps of gum on peach trees. Information regarding their life history and means of eradication was asked for.

Answer—These are the larvæ of a moth which lays its eggs upon the trees, more particularly where any gum is oozing out, and principally in the forks of the branches, or upon the trunk. Such places should be examined at pruning time, and any sawdust-like borings will indicate the presence of the insects. This evidence should be followed up by scraping away the gum and borings, and if the caterpillars have tunnelled into the wood and are out of sight, the holes will be seen. Sometimes a piece of thin wire may be pushed into the hole and the borer killed. If the tunnel is crooked, a small quantity of cotton waste saturated with carbon bisulphide or benzine may be thrust into the hole, which should be immediately plugged with clay. This will suffocate the borers. If much of a wound is made by the insects, paint it with Stockholm tar or any carbolic preparation.

WASHINGTON WHITEWASH.

"A. B." asks how to prepare Washington whitewash.

Answer—Slake a bushel of quicklime in a barrel, covering with a bag while the lime is working; melt 1lb. common glue to a thin size; make 1½lbs. ground rice into a thin paste with boiling water; mix up 1lb. whiting as you would mustard. When the lime is quite slaked, add the glue, whiting, and rice paste, and a half-peck of common salt. Mix well and let stand for 48 hours, keeping covered. Thin down to consistency of ordinary whitewash and apply hot. The White House at Washington is said to be coated with this preparation. If properly made it will neither wash nor rub off, and has all the appearance of paint.

RUSSIAN SUNFLOWERS.

"J. E. H.," Forest Range, is desirous, as an experiment, of growing sunflowers with a view to using the seeds as feed for poultry, and asks for information as to the class of seed, time for planting, &c.

Answer—The sunflower used for the purpose of feeding seeds to poultry is the large Russian type of annual sunflower (*Helianthus annuus*). It is sown at the rate of about 6lbs. per acre, and costs locally, from E. & W. Hackett, 6d. to 1s. per pound. The soil should be worked down to a fine tilth, and the seeds sown either broadcast or in shallow drills, which are from 2ft. to 2ft. 6in. apart, and the seeds dropped in about 6in. to 9in. apart. A sprinkling of superphosphate on the drills, but not on the seeds, will help. Cover the seeds about twice their own length with loose soil. They should be sown when the frosts in the neighborhood are over.

UNPRODUCTIVE POULTRY.

"J. W. H.," Mikkira, has 31 fowls; he feeds them well, but they have not laid an egg for several months. He asks for advice, and also at what age turkeys and geese should be mated.

Answer—(1) You are probably overfeeding your fowls, as you say they are very fat. There is an old proverb, "Fat hens are ill layers." As regards the Indian Games and Malays, these are notoriously bad layers, and if the crossbreds have Malay or Indian blood in them they will likewise prove poor layers. Can you get any meat for them—rabbits or plucks? If so, boil a pluck or a rabbit and then chop up and mix with a little bran, and give the birds a hot feed in the morning and use less grain. This should have the desired effect. (2) It is not advisable to breed from either geese or turkeys until they are two years old. They will certainly breed, but the progeny are inferior, and if again bred from, the stock will deteriorate in every way.

BINDER TWINE CUT WITH HAY.

"A. S. P.," Maitland, desires to know whether binder twine, i.e., the bands of the sheaves, cut with the hay and fed to horses is likely to be followed by any injurious effects.

Answer—Yes; it is likely to assist in the formation of dung balls (*calculi*) in the bowels, and cause colic.

LUCERNE AND LUCERNE FLEA.

"H. E. B.," Echunga, writes—"Can you inform me if there is any known treatment which will make it possible to get a crop of lucerne where the lucerne flea attacks the plant on its first appearance above the ground. The soil here is suitable for lucerne, being a black alluvial flat, but the flea is very prevalent in the surrounding vegetation. Repeated trials have resulted in the pest cleaning all but a few plants out. These few have always done

well. What is the most suitable variety of lucerne for a cold district? Water is at about 9ft. or 10ft. from the surface. What is the most suitable manure for lucerne? What is the most suitable manure for maize for green fodder?"

Answer—The best method of preventing the ravages of this pest on new lucerne ground, is, in the first place, to have the land thoroughly cleared of weeds before planting, and afterwards to work up from a chain to a chain and a half of land around the whole of the lucerne plot. This must be kept in a thorough state of cultivation and free of weeds; the object is to do away with any possible harbor for the pests, while at the same time the strip of cultivated land offers them no inducement for further exploration in that direction. Another method found to be fairly effective is to keep all weeds and grass surrounding the lucerne plots grazed closely with sheep. The most suitable variety of lucerne for a cold district is South Australian, or guaranteed Hunter River, or Tamworth seed. Some of the other varieties might possibly give better results under extreme cold conditions, but up to the present no special tests have been made in that direction. The manure required for the lucerne depends entirely upon the quality and nature of the soil. The safest dressing to recommend, without further information on the subject, would be a liberal dressing, say, 3cwts. or 4cwts. of bone super. to the acre, if the soil has been impoverished to any extent by previous cropping. The same remarks apply to manure for maize. Under any conditions, stable manure will give the best results if it can be procured in sufficient quantity.

STOCK INQUIRIES.

(Replies supplied by Mr. F. E. PLACE, M.R.C.V.S., B.V.Sc., Veterinary Lecturer.)

Delayed Cleansing of Cow.

The Mount Pleasant Branch of the Agricultural Bureau desire to know the best means of dealing with cows whose afterbirth is unduly delayed.

Answer—Normally a cow should clean within 36 hours after birth, but if after the twelfth hour the membranes do not appear to be coming away properly, the following drench may be given with advantage:—Epsom salts 1lb., flowers of sulphur 2ozs., powdered ginger 1oz., to be dissolved in a quart of gruel, or warm water and molasses, to which half a pint of gin has been added; if in the next 24 hours the cow has not cleaned, the drench may be repeated. The womb should be flushed out with 2galls. of warm water in which Condyl's crystals, or permanganate of potash, as much as will cover a threepenny bit, has been dissolved. The flushing may be done with the proper syringe, or failing that, equally well with a few feet of rubber gas piping and an enamel funnel. The piping is passed well into the womb and the funnel end raised well above the cow, the solution will then gravitate into the organ and well irrigate it. If this also fails to cause the removal of the membranes, the part hanging out should be secured between a split stick, round which it

can be rolled, and a gentle, steady pull kept on it, the utmost care being taken not to break it off. If this also fails, the arm should be well greased with lard and passed into the womb, at the bottom of which the membranes will be found attached by a number of button-like processes (*cotyledons*). These must be squeezed off between the first and second fingers, while a steady pull is kept on the membranes from outside. If the membranes are very rotten, owing to having been held too long, extra flushings will be required; and the operator should not have any cuts about his arm, as there is a risk of blood poisoning. If the cow remains weak she should be drenched with beer and gin for a few days.

Death of Cow.

A member of the Forster Branch of the Agricultural Bureau reports the loss of a cow. There was a considerable discharge from the nose. the animal swelled greatly at the chest, she appeared to have an abnormal appetite, and passed a considerable amount of blood with her excreta.

Answer—The statement of symptoms supplied is altogether too vague for an opinion to be given, but with the exception of the abnormal appetite it is possible that they point to malignant catarrh. The discharge of blood with the dung, however, rather points to an infestation with worms. Should other animals appear to suffer in the same way it would be well to dose them with brimstone and treacle—1oz. of flowers of sulphur to a pound of treacle or molasses every day till they have purged well, which will probably be on the fourth day.

Flies Troubling Stock.

A member of the Coorabie Branch of the Agricultural Bureau drew attention to numerous small flies which congregated around the stables, and which seemed to attack horses and cattle as soon as they came in from the paddocks. When killed, after having settled on the horse, the flies were found to be full of blood. They somewhat resembled the common house fly, but were larger, a little lighter in color, and had a long sucker. Information was sought as to the name of the flies and whether they were injurious to the horses.

Answer—In the absence of the flies it is not possible to state definitely what kind they are, but from the habits described it is probable they are a species of breeze fly (*Tabahidae*), which are very plentiful in all parts of the world. They are not bot flies (*Gastrophilus equi*), which are not blood suckers. Many of the breeze flies carry fatal diseases to animals upon their suckers, which have been inserted into an affected beast. As a preventive, the horses might be wiped over with a rag dipped in kerosine, oil of eucalyptus, or other strong-smelling oil to which the flies object. The following procedure will kill off large numbers:—Mix two tablespoonfuls of 40 per cent. formalin in a whisky bottle of water, pour equal quantities of this and milk into a saucer, and put a piece of bread into it as an island for the flies to settle

on. Put half a dozen or so of such saucers in the stable during the day. Sweep up and burn the dead flies that will be found lying about.

Catarrh and Stones in the Bladder.

A member of the Coorabie Branch of the Agricultural Bureau was experiencing trouble with an aged draught gelding. Three months ago the animal showed signs of griping pains, and drops of blood passed through the penis. It was given three doses of saltpetre, which seemed to relieve the difficulty for about three weeks, when it recurred. Further doses of saltpetre appeared to clarify the urine, but there was a continuous dripping from the penis. When turned on to green wheat the complaint became worse. The penis swelled and broke out at the end, and there was a discharge of blood and matter from it. Bran mash and saltpetre administered during the past week seemed to have had little effect.

Answer—Old horses, such as the one in question, frequently suffer from catarrh of the bladder, with stones (*calculi*) in it and in the pipe through which the urine passes; this appears to be the trouble in this case. It would be well not to give any more saltpetre, which, although good in many cases, is likely to prove an irritant in this; instead, let him have in a bran mash, or as a drench if he will not eat, in a pint of barley water, made from pearl barley, two drams of bicarbonate of potash twice a day for five or six days; also, if drenching, a dram of powdered camphor twice a day. The organ should be washed twice daily with warm water and a good household soap, such as "Sunlight," and then dressed with olive oil, in which half an ounce of powdered camphor to one pint of oil has been dissolved. Keep the horse on soft feed, preferably green stuff, but not lucerne, and let him drink very freely. Two ounces of the camphorated oil might be injected up the pipe by means of a glass syringe with advantage.

"C. J. W.," Port Lincoln, asks—(1) In order to save handling costs and waste, can chaff be stored in bulk in a large shed, it being chaffed into same directly it is carted from the stooks and not stacked at all? (2) If the hay was chaffed directly from the paddock into an airtight silo and weighted, would the chaff be as good for horses as chaff made from stacked hay?

Reply—(1) In order to get hay sufficiently dry to be chaffed and stored in bulk without stacking it would be necessary to leave it too long in the field. Each day it is left increases the amount of weathering, and, of course, increases the risk from broken weather. Altogether, it would be an unprofitable practice and not to be recommended. (2) The proposal to chaff hay direct into an aerated silo, and press it down with weights, is not one to be advised. The chaff would grow more or less mouldy around the outside from the sweating in bulk. It would be more or less fermented, and would be dangerous to feed to horses. To chaff into the silo the stuff requires to be cut green, and only slightly wilted.

TAINTS IN MILK AND ITS PRODUCT.

THE NECESSITY FOR CLEANLINESS.

By H. J. APPS, Dairy Officer.

The susceptibility of milk to taints is at no time more strikingly manifest than in the spring and summer months of the year. The weedy flavors are more prevalent when the food is succulent and abundant, as the pasture then invariably contains a large proportion of herbage which impart gaseous taints. Thus one is inclined to attribute all taints to the class of foods which the cows receive. This is in a great measure responsible for some, yet another factor, which tends to affect the physical condition of the milk, is the invasion of filth organism, due to the lack of cleanliness and attention bestowed to the milk and cream.

Obviously, then, some of the taints or bad odors can be to an appreciable extent minimised. This is especially the case in so far as the influence of milk is concerned, when we observe how readily it becomes contaminated and also when we consider to what degree weeds exert their influence by imparting bad flavors, the milk in some instances having a pronounced weedy flavor. So long, however, as the taints exist in the milk and cream, the quality remains inferior, and the market price realised is not so great as for fine-flavored milk or its products.

It is impossible for the factory manager to manufacture really first-class cheese or butter from milk or cream which is pronouncedly tainted. In some cases, however, where rigid grading is enforced, it is within his power to prevent the bulk of the cream from becoming contaminated by the addition of such cream. In cheese-making it is harder to cope with the defect unless the manager introduces a pure starter or culture of lactic acid to overwhelm the gas-forming organism. Many dairymen have not so good a conception as they should have of the ease of contamination. The warm milk as it comes from the cow is a splendid medium for the growth of all kinds of bacteria which may gain access to it. In order to lessen this development, every precaution should be taken to guard against their invasion right from the time the cow is being milked until the cheese or butter is manufactured.

There are, of course, several influences, such as health, treatment of the cows, feed, water, cleanliness, &c., that more or less affect the character of the milk and its products. Impure water is probably one of the most potent factors; anyone allowing his cow to drink such water must be conscious of the ultimate results. The water used for washing the dairy utensils occasionally is not renewed sufficiently to guarantee the proper cleansing of the

utensils. It is far too common to find that in washing the bowl of the separator it is placed immediately into the washtub together with the other appliances, instead of first being thoroughly scrubbed free of the filth or slime that adheres to the inside portion, and that one lot of water only is used for the whole washing process. Unless the farmer gives never-ceasing attention to his produce he cannot expect to attain success. The careless dairyman is gradually awaking to the advantage of this all-important fact in connection with the care and treatment of the milk and cream. It certainly behoves him to do so, especially as the majority of the factories are now paying according to the quality of the produce. This is the only legitimate method to employ, for why should the dairyman who takes no particular care of his milk or cream secure just as high a price as the man who is continually paying attention to the condition in which he delivers the product. As dairying becomes more firmly established there will be less complaints concerning the taints in the produce. Once the farmer has built up a good paying herd, he will make provision for cultivating and laying down good pastures for his stock, and will also give more attention to the treatment of his milk and cream.

CARE OF MILK.

Where a large number of cows are milked it is a good plan to allot the work of bailing up and washing the udders of the cows to one man. This lessens the possibility of introducing filth, &c., into the milk, besides greatly facilitating the work of the milkers. If the udders of the cows were in all cases either washed, or at least wiped with a damp cloth, previous to milking, it would reduce the number of bacteria in the milk by fully 80 per cent. when compared with udders that have not been so treated. The milk should be removed from the cowshed as soon as practicable after milking, so as to avoid the danger of absorption of odors. All milk should be passed through a strainer; a very fine mesh wire strainer is preferable to cloth, unless the cloth is thoroughly washed after each milking. The strainers should be occasionally cleaned during the milking. It is an accepted fact that the fine flavor and keeping quality of butter is largely dependent upon the treatment of the milk right from the time it is drawn from the cow until the cream is about to be churned.

In several cases the animal heat or odor and various taints can be greatly eliminated by cooling and aerating the milk. Should the milk be separated immediately after milking it may be merely aerated by allowing it to run over the cooler without any water circulating within the coils of the cooler; but such a procedure must be done in a sweet atmosphere. The nearer the temperature of the milk to that when it leaves the cow the better the separation; but it is imperative for good results that the cream be aerated and cooled as it is leaving the separator. Proper aeration implies two essentials—that the milk be warmer than the surrounding atmosphere, and that the air itself

be purer than the milk. Animal heat is always present in milk, and to ensure the best as regards future products it should be removed. Milk is prone to decomposition—it has a constant tendency towards acidity on exposure to the air—thus the vigilant necessity for its preservation is increased. When

Types of Milk-Coolers.

milk is intended to be kept for some time before separation it should be cooled as well as aerated to a temperature below 60° F., as this checks the action of various germs.

Under no circumstances use the milk from freshly-calved cows for at least before the tenth milking, and in some instances the time will require to be extended. Inclusion of milk from cows suffering from any affliction of the udder, inflammatory or otherwise, only tends to reduce the quality of the remainder. Unhealthy cows, rusty and foul-smelling cans, dirty separators, etc., are conducive to the greater number of taints and odors in milk.

FEEDING.

Cows fed on foods which impart a taint to milk should be fed sparingly and immediately after milking. This will to a great degree minimise the danger of such taints.

IMPORTANCE OF VENTILATION.

Milk rooms, as well as the bails, should be scrupulously clean, being kept free from bad odors of any kind and as dry as possible, as no food so easily absorbs odors as milk. The floors, walls, ceilings, &c., should be free from all impurities, and spilt milk should not be allowed to decompose. In some cases where precautions are not exercised more danger is likely to follow aeration and cooling than if no treatment was employed, as for example when the atmosphere is bad and the temperature greater than that of the cooling point, the power of absorption being greater when the atmosphere is higher in temperature than the milk.

CLEANING DAIRY UTENSILS.

Dairy utensils should first be rinsed with cold water to remove all particles of milk. Then they should be thoroughly scrubbed with a scrubbing brush in hot water containing $\frac{1}{2}$ per cent. of washing soda. After this they should be well steamed, or at least rinsed in boiling water, and finally placed away in a well-ventilated spot. It is strongly recommended that a liberal supply of limewater for washing floors, utensils, &c., be constantly used.

Washing the separator is not a very difficult operation if done soon after separating. The water for washing should be warm, but not hot enough to cook any portion of curd that may be present. Never allow the separator to be placed together unless just before using the machine. Whilst the parts are disconnected see that each part is properly separated and well exposed to the air. If not well aired a foul smell soon arises. This odor is invariably imparted to the cream whilst being separated from the milk.

If a cooler is not available, or the water is not sufficiently cold, the can containing cream should be placed in the coolest spot and the contents occasionally stirred. If the can is placed in water the lid should be removed, thus giving the animal odors a chance to escape. A clean dry cloth may be substituted for the lid as a protection from dirt, &c.

The first as well as the last requisite is cleanliness.

(To be continued.)

THE POULTRY TICK.

By D. F. LAURIE, Government Poultry Expert and Lecturer.

[Paper read before the members of the Microscopical Society of South Australia, June 25th, 1912.]

(Continued from page 19.)

THE LIFE CYCLE OF THE TICK.

Plate 15.—Micro-photograph. Ova (eggs) in body of tick in Plate 14 x 45. This illustration shows the central and left-hand ova seen in Plate 14.

PLATE 15.

PLATE 16.

Plate 16.—Micro-photograph of ova (eggs) of tick x 45. The ovum on the right-hand shows a typical egg. The egg is about .05 m.m. long by .04 m.m. broad; in color it is a shining dark reddish-brown, enclosed in a fairly tough chitinous membrane. On examining a jar of ticks recently

collected, numerous eggs will be found; some on the bottom of the jar, others temporarily attached to the backs and legs of the ticks. Hatching occurs in due course, about three weeks, according to Lounsbury; but I think the time must be less. Nuttall says 11 to 13 days. However, one must very carefully examine all the ticks before consigning them to the specimen jar, as it frequently happens that larvæ will be found attached to the old ticks. In nature the tick lays her eggs in cracks and crevices, although I have found them on the body of the fowl on several occasions, but have not recently obtained specimens for illustration, the practice being uncommon.

I believe the tick to be occasionally viviparous, as I have on three occasions seen a female tick on the side of a glass specimen jar deposit a young tick

PLATE 17.

surrounded by a transparent jelly-like mass, from which it emerged in a few minutes. I have examined and observed carefully hundreds of specimens during the last few years, but have not witnessed a recurrence. On the last occasion there was also present a trained observer, who died some years ago. He was convinced of the fact as we saw it.

Plate 17.—Micro-photograph of eggs and young ticks x 24. The centre egg was ruptured in the process of mounting, the others show the characteristic shape. The young ticks (larvæ) are interesting, especially the right-hand

lower specimen, which shows the undigested egg yolk in the digestive cæca very distinctly. When examining a live tick, at any stage of development, and after feeding, the peristaltic action of the digestive organs is most interesting to observe.

Plate 18.—Micro-photograph of young tick (larva) x 24. This specimen is a newly-hatched tick, and is known as a larva. At this stage the young tick has three pairs of legs only, and is light-grey in color, and moves like an ordinary long-legged spider. The body is circular in form, viewed dorsally, and the mouth parts and palpi are very prominent anteriorly. The palpi and rostrum are very clearly shown in this plate. It has no spiracular nor genital orifice. The tick at this stage is very small, averaging about .75 m.m. long by .70 m.m. in breadth. At this stage the casual observer, including most poultrymen, would not notice their presence on the woodwork of the poultry houses, and if observed would be confused with ordinary unfed mites.

PLATE 18.

In this stage they are frequently attached to the adult ticks, and are carried to the host, the sleeping fowl. Others, and the greater number, reach their prey by the aid of their own legs and marvellous sense of smell, or something else. They move as soon as their chitinous covering has hardened. They feed for five to 10 days, and swell considerably, appearing as blue-black spots on the fowl.

Plate 19.—Micro-photograph of larva x 24. This specimen has not only fed, but his body shape is in process of alteration. The rostrum and palpi are seen closed together; the blood of the fowl is to be clearly seen in the digestive tract, and the specimen was almost gorged with blood.

Plate 20.—Micro-photograph of larva x 24. This shows a young tick from the duck's neck, *vide* Plate 10. This tick was well gorged and considerably changed in shape, as was the case with those shown on the fowl in Plate 13. This tick left the duck's neck, having evidently satisfied its appetite.

The gorged tick is of a blue-black color on the host ; when preserved the specimens are often reddish in color. The gorged ticks, as has been stated, change in shape, the body becomes oval, and the characteristic markings of the adult appear. After gorging themselves, they retire to a crevice to remain dormant, digesting their meal. They then, at the end of a few weeks, shed their old skin (moult) and acquire their fourth pair of legs and the spiracles (breathing organs). They are then known as nymphs, of which there are two stages.

PLATE 19.

PLATE 20.

Plate 21.—Micro-photographs of mouth parts of tick in Plate 20 \times 100. This interesting plate shows an enlarged view of the mouth parts of the young gorged larva shown in Plate 20. The armed mandibles are very distinctly seen, with the saw-toothed cutters. The body outline is visible, and shows that the hood has extended and so nearly covered the capitulum that without magnification the mouth parts cannot be seen from the dorsal view.

Plate 22.—Micro-photograph of young ticks x 7. This shows the dorsal view of a nymph and a small tick. In both the digestive caeca are plainly shown, more particularly in the nymph. The demarcation in the latter is due to the presence of ingested blood.

PLATE 21.

PLATE 22.

PLATE 23.

PLATE 24.

Plate 23.—Micro-photograph of young tick x 7. Here we see a dorsal view of a young tick (nymph) which, like the larger one on Plate 22, is rather more than half grown. Careful examination is necessary to distinguish

the sexes. The female is the larger and thicker of the two, but a small female and an adult male are alike in many respects. The genital orifice of the female is longer than that of the male.

Plate 24.—Micro-photograph of mouth parts x 24. This shows an enlarged view of the mouth parts of an adult female tick. Immediately posterior to the capitulum, or base of the mouth parts, the genital orifice can clearly be seen. This slide is one of Mr. Poole's, and gives most interesting details of the palpi, mandibles, and also of the integument of the underside of the tick.

Plate 25.—Micro-photograph x 7. This shows the ventral aspect of a medium-sized tick (nymph). The mouth parts are clearly shown, and the detail is distinct. They are two stages of the nymph. Nymphs feed rapidly

PLATE 25.

PLATE 26.

one and a half to two hours. After a feed they moult. In a few weeks they feed again, then moult and emerge as the adult.

Plate 26.—Micro-photograph of mouth parts of medium-sized tick x 45. This plate shows the dorsal view of the mouth parts of a medium-sized tick. The integument forming the hood has been reflexed, thus exposing to view the upper surfaces of the mandibles and palpi. The detail shows the bulbous muscular attachment of the mandibles.

Plate 27.—Micro-photograph x 8. This is the ventral aspect of a fully-matured tick. Not until full maturity do the genital orifices appear. The genital orifice is situated just behind the mouth parts and, as stated, the male by inserting his rostrum transfers the spermatophores into the female orifice. In a sunny room where jars of tick are kept this peculiar act may often be

observed. The genital orifice is seen at "A." Asymmetrical (uneven sided) specimens are frequently met with. This specimen appears to belong to that class.

Plate 28.—Micro-photograph of spiracle x 200. This highly interesting plate gives a splendid picture of a spiracle, one of the breathing tracheæ, of the tick. In the larval stage the tick has no spiracles, they appear after the first moult and with the fourth pair of legs (in the nymph). The action of destructive agents, such as kerosine emulsion—with or without oil—tends to cause a gathering of dust, &c., which fills up the spiracular orifices and causes asphyxiation.

PLATE 27.

PLATE 28.

Plate 29.—Micro-photograph of full-grown tick x 6. A normally shaped adult female tick, viewed ventrally. The shape is characteristically oval and symmetrical. The mouth parts and their exact position on the adult are well shown, and we have a clear view of the position, attachment, and articulation of the four pairs of legs, each armed with its claws.

Plate 30.—Micro-photograph of mouth parts x 60. This enlarged view shows clearly the rostrum and palps, the articulation of which is distinct. The characteristic saw teeth of the mandibles is also seen, and some detail of the integument also.

Plate 31.—Micro-photograph of full-grown tick x 6. This photograph is from one of Mr. Poole's slides, and is highly interesting, as it clearly shows

the peripheral margin referred to in the description of the tick. In addition, in this typical specimen are seen the attachments of the coxæ of the limbs, the claws, and the mouth parts. In the foregoing descriptions sufficient explanation has been given to enable the practical poultry breeder to recognise and, if desired, study the tick and observe its habits in the various stages.

PLATE 29.

PLATE 30.

PLATE 31.

WHY TICK-INFESTED POULTRY DIE.

For many years I was at a loss to account for the deaths of fowls in many cases where there were comparatively few ticks present. In discussing the question, some six years ago, with Dr. A. A. Brown, of Victoria, I remarked that I was convinced that the tick left something behind in the bite. I asked Dr. Brown to follow this line of research. On visiting Melbourne some months later, Dr. Brown stated that he had discovered a protozoon which he believed was the cause of the septic symptoms. I was not aware at the time that important discoveries had been made in Brazil by Marchousi and Salimbeni; and that Balfour, in the Sudan in 1906 (the year I saw Dr. Brown), discovered the same causative organism. I had on many occasions noted that fowls which were swarming with larval ticks, and attacked at night by adults and others, did not die, but became emaciated and weak. After destroying the ticks adhering, and removing the fowls to clean quarters, they invariably recovered. Others, again, when perhaps only two or three larvæ were found attached, and only a few adults, &c., in the woodwork, exhibited symptoms of tick fever, prostration, high temperature, and early death. It seemed that the only explanation was that some ticks were apparently venomous, and others merely weakened the fowls by sucking their blood. The discoveries in Brazil, the Sudan, and elsewhere, gave the required explanation and confirmation.

In Queensland (1908) Dodd discovered the organism known as *Spirochæta Marchouxi*. In 1911 Gilruth announced the discovery in Victoria, and shortly after J. F. McEachran, M.R.C.V.S., the South Australian Government Chief Veterinary Surgeon, made some experiments with ticks procured by me from the north of this State. As a result of his work the spirochæte was demonstrated as the causative agent of tick fever among poultry in this State. Jowett reports the occurrence of this organism at the Cape. I do not propose to consider the life history of the spirochæte, as I have no personal records. I propose investigating the matter at a later date. The spirochæte, although only visible with the higher powers of the microscope, is a comparatively large organism. Jowett records some as 25 and even 30u in length and with 7, 8, or 9 spirals ($1u = \frac{1}{25000}$ of an inch). In the reports quoted, those interested will find detailed accounts.

Dodd reports that the spirochæte, in cases of inoculation from fowl to fowl, soon loses virulence unless reinvigorated by passage through a tick. Balfour, however, states that this refers to adult fowls and not to chicks. The tick, while feeding, discharges from the inter-coxal spaces a fluid. Balfour states that this fluid contains the spirochæte, and thus the site of the bite is infected.

IS THERE A CURE FOR TICK FEVER ?

Poultry breeders whose premises are tick-infested constantly report large losses among their poultry. For some time many of these outbreaks of

sickness were puzzling. With extended experience it soon became apparent that diseases of a generally similar character could in practically every instance be traced to the tick. Prompt eradication of the pest generally saved the remainder of the hitherto unaffected birds. Comparatively few fowls recover from tick fever, or spirochaetosis, as it is scientifically termed. In the hands of the ordinary breeder there is no known remedy. Dipping, or the application of some tick destroyer, such as kercsine and oil, certainly gives the bird a chance; but as a rule the damage is done and the blood is swarming with the organisms.

Dodd reports having experimented with injections of one of the organic arsenic compounds, soamin (syn atoxyl) (para-aminophenylarsonas) ($C_6H_7NAsO_3Na$). Doubtless some excellent results would occur from the use of one of the more recently investigated arsenic series.

Balfour quotes from the reports of several investigators who have used the now celebrated "606" (salvarsan) or dioxydiamido-arseno-benzol with excellent results.

It is my contention, however, that the proper procedure is to eradicate the tick. As long as ticks are allowed to infest premises, so long will it be unsafe to keep poultry. Further, as it is known that ticks occasionally bite human beings and seriously incommode them for some weeks, the destruction of the tick is all the more imperative. To bring about this much-desired state of affairs has prompted me to direct attention to the tick and its habits.

The free use by spraying, and even soaking the poultry houses, fences, &c., with 10 per cent. kerosine emulsion will very soon destroy ticks, but old harbors must be destroyed.

GRAPE VINE PRUNING FOR AMATEURS AND BEGINNERS.

By GEO. QUINN, Horticultural Instructor.

(Continued from page 30.)

THE THOMERY SPALIER.

This is the spalier most commonly applied by growers to table-grape vines when planted in strong soils, as well as by irrigationists in the production of grapes for raisins.

TYPE.

The type consists of a perfectly vertical stem carried to such a height as may meet the requirements of the trellis, as described later; and out of this, on a level with the wire or other support against which they will be secured, two arms emerge in a horizontal position, making on each side, as nearly as possible, a right angle with the stem. On these main arms the fruit-bearing shoots, consisting of spurs and rods, or spurs only, as the variety demands, are located at distances as nearly equal as possible apart. The general practice is to establish the spurs 6in. to 9in. apart when used alone, and rods accompanied by spurs are not permitted to remain closer than from 15in. to 18in. distant from each other.

FORMING THE VINE.

Assuming the newly-set plant has been pruned back to one spur of one or two buds only during the previous winter, in the early summer a strong shoot is encouraged to grow from one of these in a vertical position. To secure exactness, as soon as the height desired for the stem is reached, attention should be given, and when this point has been passed by several leaves upon the tender tip of the shoot, this tip should be pinched off back to the bud immediately underneath the desired height (see (a) Fig. 21). In a few days another shoot arises from this bud, but being weak at the start, it forms very close joints, *i.e.*, short spaces between the buds. This shoot is nipped off at the point as soon as it reaches about an inch in length, but its successor is allowed to persist and gather strength for the remainder of the summer. The distances, however, between the lowest buds upon it remain unlengthened (see (b) Fig. 21).

At the next winter pruning the shoot is cut off at the desired height just above where the growth started last summer after the second pinching was administered (Fig. 21 (c)). Here two buds will be found almost on a common level which, in the coming spring, will usually start as these have done upon (b) Fig. 22. The average vinegrower, however, will not give the necessary attention to secure these exact results, and the writer knows of many instances of well-balanced arms being secured by following the practice of one summer pinching, as illustrated in (a) Fig. 22. In this the shoot is trained up against a support vertically—a tall stake will answer until the desired height be attained—when it is pinched off to the bud immediately under that point. The young growth which rises from the top bud usually makes a weakly

Fig. 21. — Forming the Thomery Spalier, dotted lines showing positions of (a) First Pinching in Summer, (b) Second Pinching in Summer, (c) Next Winter's Pruning.

start with several internodes, each only about an inch long; but as the shoot swells these appear to shorten, and when at the next winter pruning the shoot is severed at the wire, or position where the top of the stem is to be, the growths resulting from the two topmost buds emerge sufficiently near to a common level to secure for all practical purposes evenness of balance to the main arms of which they are the foundation.

Whichever of these methods are adopted, the shoots from these two buds are encouraged during the next summer to make strong growth. After they have extended about 1½ ft. and lost their brittleness, they should be bent down to a horizontal position. Although this operation retards to a certain extent their vigor, it is essential for the purpose of securing that perfectly

horizontal direction which could not be so readily reached when the shoots have stiffened to the degree attained by them when the next winter pruning season arrives. When this time comes around the vine will have assumed the shape indicated by (b) Fig. 22, with the exception that small laterals will probably have grown from some of the buds upon the horizontal arms. These arms are now shortened back to a length which may vary with the respective vigor of each, the weaker one being shortened more than the stronger. In no case should these arms be retained to a great length—about 3ft. or 4ft. is quite long enough for the most extended development, whilst on the average from 1ft. to 2ft. will be safer lengths to adopt. The danger of allowing long extensions during the first season or two arises from

Fig. 22.—Forming the Thomery Spalier. A, Shoot with ordinary development after being pinched once in Summer; position of Second Winter Pruning dotted. B, Resulting growth before Third Winter Pruning at dotted lines.

the fact that the buds upon such arms rarely break into growth with the regularity desirable, and consequently unduly long spaces remain unfurnished with fruiting wood. When severing the canes which are to be laid down for main arms, care should be taken to bend each one into the horizontal position it will assume when tied, and then cut it off *through the node immediately beyond a bud which occupies a position upon the underside of the cane*. The section is cut through the node, or bud knot, to permit tying operations being performed with complete safety to all buds upon the cane. The reason for retaining the terminal bud upon the *underneath* side of the cane is to

ensure that *the curve made by the terminal shoot shall lie below the line of the parent cane*. Such a curve will straighten up as time passes, but the bend made by growth from a bud situate upon the top side of the cane does not readily sink to the level of the rest of the arm even after the lapse of many years, and during all of that time it acts as an impediment against the free flow of the sap to the portion of the arm situated farther out. If any small laterals have arisen from these horizontal canes during the first summer they should not be cut as spurs, but suppressed completely, as a bud to be seen at the base of each one will replace them in the coming summer. It goes without saying that any side shoots upon the stem, or suckers from beneath, should have been suppressed in the previous summer; but if any such remain at this winter's pruning they must be completely eradicated.

The appearance of a Thomery spalier before receiving its fourth winter pruning may be seen at Fig. 23. It will be noted that the buds upon both arms

Fig. 23. Thomery Spalier before Fourth Winter Pruning.

have, without exception, grown into fairly strong shoots. They are, however, much too closely placed upon the parent limbs, and many must be suppressed. The attention of the reader is drawn to a shoot emerging from the arm on the right of the picture, near to its junction with the main stem. This shoot is the most vigorous on that side. This vigor is due to its close proximity to the main stem, and thus obtaining more than its share of the sap. It demonstrates the necessity for observing a rule in designing the Thomery spalier, which *forbids the retention on the main arms of any spur or secondary arm within about a foot of the main stem*.

The pruning recommended for this vine is illustrated in Fig. 24, where it will be seen, besides the continuation rod, only two spurs have been retained

on each arm, and these are about 9in. or 10in. apart. The extension rods at each end have been cut about 15in. long, and the underneath buds have been again selected at the end of each rod. The downward bend upon the annual extension of the arm on the left of the picture is very pronounced, but the "pull" of the sap will straighten this up to the wire after a year or two has elapsed.

Fig. 24.—Thomery Spalier after Fourth Winter Pruning.

The after pruning of this vine would consist each winter of maintaining these spurs upon permanent arms, adding others on similar lines along the extension of the previous season, and laying down a short extension rod or spur until the space allotted to the arm be filled. From time to time, here and there, an exaggerated spur which has really become a short, crooked, secondary arm, must be shortened back to a watershoot which has arisen from its base or from the main arm, either at its junction with the old spur or thereabouts. A spur-pruned Thomery spalier of mature formation is illustrated in Fig. 25.

Fig. 25.—Mature Thomery Spalier; Spur Pruned.

In the case of such varieties of vines which need spur and rod pruning, instead of one shoot of the pair which arises from each spur being suppressed, that one farthest out from the main arm is cut to a rod and bent down, whilst its fellow arising from the bud nearest to the bottom of the spur is itself

pruned to a spur to supply two shoots for the next season's work. This rod, after bearing its fruit, is cut away completely at the next winter's pruning. This is shown in Fig. 26, which represents the modification of the Thomery spalier as adopted so successfully by the late Mr. Thomas Hardy, of Bank-side, in the growing of the Zante currant. In this the great vigor displayed by the currant vine is allowed to expend itself in a larger number of spurs and rods, without massing the foliage and excluding the light from the buds and bunches beneath to the extent which takes place when all the shoots are distributed on the same plane as that assumed by the stem.

Fig. 26.—Hardy's T-piece Form of Thomery Spalier, used in growing the Zante Currant
A, Elevation of Trellis.

B, Ground Plan ; Vine viewed from above, showing spurs and rods.

The Sultana vine, depicted in Fig. 27, shows the type of Thomery spalier found most applicable to the training of that variety. This vine, it is true, is badly designed ; but the reader's attention is drawn to the very short main arms—not above 2ft. long—although the vine is about 12 years old. This modification is suitable to all vines the main arms of which have a tendency to run into spaces bare of spurs if extended far away from the trunk.

Among table grapes, Waltham Cross and Centennial display this tendency very freely. The pruning suggested for this vine is given in Fig. 28, from

Fig 27.—Sultana Vines trained as Thornery Spaliers with Short Arms.

Fig. 28.—Thornery Spalter ; Pruning suggested for Sultana Vine in Fig. 27.

which it will be seen that the effort of the pruner is directed towards forcing out from the spurs on the main arms a number of very strong rods each season, about half of which are cut back to spurs, whilst a number—which

varies with the vigor of the individual plants, and even with that of the arms on the same plant—are retained for bearing the fruit in the coming season. These rods are twisted at the base and tied round in an arched form to the wire supporting the main arm, or raised to the next wire, around which they are freely twisted. When the vine is pruned the horizontally-trained annual rods are not used for the further extension of the main arms, consequently they are also twisted around the wires. The twisting recommended for the fruiting canes causes a steadier flow of the sap to the extremities of the vine. This reacts favorably upon the spurs, assisting in the production of

Fig. 29. - How to Cover High Trellis Work with Vines trained in Thomery Spalier (after Foëx). From "Vino Pruning," by A. T. Perkins.

a strong growth of canes for next season's use. It also regulates the supply to the buds upon the twisted canes themselves, assisting those situate near to the main arm as against undue absorption by those located towards the outer end, which otherwise would monopolise most of the vigor. The twisting should not be performed until the sap begins to move in early spring, otherwise the canes are too dry and brittle, snapping off too readily when bent. A strong-growing vine pruned thus tends to produce watershoots somewhat freely; but this, under intense cropping, has advantages in affording ready means of replacing spurs which fail to respond after the pruning—an effect somewhat common with the Sultana.

The Thomery spalier is adaptable to most vines when planted for the purpose of covering unsightly fences, high blank walls, training over lean-to structures, or pergolas for the formation of shady walks. In such cases several tiers of vines with stems of various lengths are utilised with ease.

HIGH TRELLISES.

In covering a high structure with trellised vines it becomes necessary to train a series of vines with stems of various heights, so that the rule of maintaining the fruiting wood upon a common level on each plant may be

Fig. 30. - Vines Trained on a Gable-roofed Pergola. (The short cross lines indicate the positions for severing the canes each winter).

followed. To secure the necessary length of stem it sometimes takes several seasons to grow a shoot to the required height. If the growth from the young vine does not ascend sufficiently far above this required height during the first summer, it should at the next winter again be pruned back to a spur of a couple of buds to induce a vigorous response, and only one shoot should be allowed to grow therefrom. This is tied up vertically, and as it passes the required height its point should be pinched out in the summer, as previously described, for the purpose of securing short-jointed wood with closely set buds upon it.

If a high vertical surface is to be covered, such as is depicted in Fig. 29, the method adopted there may be followed in a series of five vines. If, however, the soil be good and the grower has a wall not more than about 16ft. high to cover, the series may be reduced to two vines, *i.e.*, a short-stemmed vine alternating with a long-stemmed one throughout, as is shown in the shaded walk or pergola drawn in Fig. 30.

In designing any of these trellises the lowest vines should have stems from 1ft. 9in. to 2ft. in length, but not less. In the case of gable or lean-to structures shown at Figs. 30, 31, 32, 33, the stems of the highest should be trained along the eaves. The annual shoots will then rise each season from the lowest vines and cover the side or vertical face, and those from the higher

Fig. 31.

extend from the eaves to the apex. If the vines be spur-pruned types, each season's winter pruning is reduced to the simplest form, consisting merely of cutting the annual growths back to spurs situate close down upon the horizontal arms, renewing any from watershoots from time to time as the case demands. Fig. 31 represents a cottage wall shaded by a lean-to structure carrying one short-stemmed spalter made of a Gordo Blanco vine 18 years old. This vine looks badly designed, but its stem has been buried by filling up the land, and the main arms raised on to higher wires than those upon which they were originally framed. This can be more readily understood by referring to Figs. 32 and 33, which show this vine without leaves, before and after

pruning respectively. On this trellis the central post supports a spalier which was also divided for a lower trellis, thus causing the main arms to be

Fig. 32.—Vine in Fig. 31 before Winter Pruning.

Fig. 33.—The Vines in Figs. 31 and 32 after Winter Pruning.

badly placed also. This vine is a Waltham Cross, and is rod and spur pruned, the fruiting rods or canes being bent down, as seen in Fig. 33. The vines

at the ends are of the Muscat Hamburg variety, trained as cordons and spur-pruned. These photographs serve to show how grape vines may, if trained on the principles outlined herein, be kept over a period of many years, not only in a fruitful condition, but each summer providing a perfect shade from the *ground upwards*, whilst, after they are pruned in winter, the walls or walks may receive the fullest volume of sunshine to warm and dry them.

CORDONS.

This term is applied to trellised vines which have one main arm only, produced from the main stem. Upon this arm the annual shoots are arranged in exactly the same manner as those upon the main arms of the spalier. The cordon is superior to the spalier, inasmuch as it is more simply formed, and the trouble of balancing the growths on each side of the main stem, more particularly after the vine is furnished with fruit wood, is avoided. Further, in exposed positions the cordons may be trained with the prevailing wind, thus averting considerable buffeting and breaking off of the shoots in the early stages of their growth. Another advantage is that, whilst in the centre of the spalier there are about 2ft. of main arm space on which it is unsafe to permit any fruiting wood to grow, in the case of the cordon there is only half this length on each vine devoid of fruit wood, and that space is readily utilised by causing the terminal end of the main arm of one cordon to lengthen until it overlaps the bare space on the next.

There are many forms of cordons, known respectively as vertical cordons, oblique cordons, and horizontal cordons. In the vertical cordon the main stem is simply extended a little year by year straight up the vertical surface of a wall or other structure, and the fruit wood disposed at regular intervals along its length. This is a very difficult plant to control, for the reason that it violates the primary rule whereby it is possible to obtain an even diffusion of sap in the annual shoots.

Oblique cordons are so called because of the projection of the main stems or axis in an oblique direction. This is also clothed with fruit wood along its length, and it is likewise open to the objection raised against the vertical cordon, viz., the difficulty of maintaining an even distribution of the sap to all parts of the vine, though usually not to the same degree as with the more vertical method. If planted in series against high trellises only the upper half of the stem on a vertical or oblique cordon carries fruiting wood.

The forms of the cordon which have found most general acceptance in the vine-growing countries of the world are those possessed of a horizontal main arm, thus permitting the most permanent results being obtained from the manipulation of the fruiting wood.

HORIZONTAL CORDONS.

The principal authorities on the training of the vine have described three types of horizontal cordons, viz., the Guyot, Sylvoz, and Casenave. The former, which is suitable to rod-pruned varieties only, may be briefly described as a short-stemmed vine, carrying one spur and a rod. The rod is bent down and fixed to a horizontal wire, and the side shoots from it are severely summer-pruned. The growths from the spur are tied up to a vertical stake to assist their vigor. Each winter the rod of the previous year is cut away, and of the two shoots from the spur one is laid down for a fruiting rod, whilst the other—usually that one situate closest to the parent stem—is cut to a spur of two buds to provide the wood for next season's operations. This type has not met with the approval of Australian vignerons, being, it is said, not suited to our conditions.

The Sylvoz cordon consists of a main stem which is raised to the desired height and then bent over at right angles and produced from year to year along in a horizontal direction. The fruiting wood is pruned to spurs at first, but afterwards retained as rods only when the vine is fully formed. These rods are bent down sharply to a lower wire and tied pretty well in a vertical position, or at right angles from the main arm. The system appears simple, as each year the rods of the previous season which have fruited are suppressed back to the shoot nearest the main stem, and this is bent down as a rod to do duty as its parent did in the season just past. In practice, however, the attempts to bend the rods with sufficient abruptness to force the growth from the buds upon their lower or basal portions have resulted in a very large percentage of them snapping off. When not bent sufficiently the buds upon the terminal portion of the rod make the most growth; and, in fact, in spite of their inverted positions, seriously rob those situate nearer the main arm. Anyone practising this method of training would act wisely in allowing the rods to remain unbent until the sap has started in them, when they withstand sharp bends, and even twists, to a very much greater extent than in the dormant winter season. This system, like Guyot's, is suited to rod-pruned vines only. It needs a three-wire trellis, and Mr. A. J. Perkins, the Government Viticulturist of this State, recommends the lower wire to be set 20in. above the soil; the middle one, on which the main arm is trained, 16in. higher; and the upper wire, to support the annual shoots, 20in. above the second wire. This means a trellis 4ft. 8in. above the soil, and in most places it would prove an expensive structure.

THE CASENAVE CORDON.

This is the form of cordon which has proved most appropriate for our conditions, and is gradually superseding all others. This cordon consists of a vertical stem grown to the height desired, and thence turned at right angles along a horizontal wire or support. Along its length, at intervals of

12in. to 15in., are disposed a series of rods and spurs on such varieties as need rod-pruning. If of a spur-pruned variety, the spurs are allowed to remain closer together, say, from 8in. to 10in. apart. If for rod-pruned kinds, set

Fig. 34.—Two-year Old Vine, Unformed.

in open land, three wires are necessary in the trellis, arranged as for the Sylvoz cordon, the middle one carrying the main arm of the vine, the lower supporting the bent-down rods, and the upper the annual wood. In modifications, however, two wires only are sometimes used, as seen in Fig. 39, the rods being tied over to the wire which carries the main arm. If three wires are used, the bottom one may be 12in. above the soil, the middle wire 24in., and the upper one 12in. to 15in. above the second wire. In the case of spur-pruned varieties, two wires are sufficient—one to carry the main arm 2ft. above the soil and a second to support the annual shoots, stretched at about 15in. to 18in. above it.

FORMING THE VINE.

As in the case of all previously described vines, the newly-set plant is pruned to a short spur. During the next summer its growths are trained up a stake. If time be available, the energy of the plant may be directed into one good shoot; and this, after passing the desired height for the stem, could be bent along the wire which shall carry the main arm. Usually, however, the plant is permitted to make a number of shoots and laterals during the first summer, and 12 months after planting, when the second winter's pruning time arrives, the plant resembles the vine in Fig. 34. In

such a case the growth of the strongest cane is sufficiently stout to permit the main arm being laid down; and in Fig. 35 this has been done, and about

1ft. of the arm has been laid along the wire, all other shoots being completely suppressed. When about to perform this work the cane which is to be saved as a main arm is bent down along the wire, and at the length where it is to be severed a bud situated on the *underneath side* should be selected

Fig. 35.—Two-year Old Vine Cordon-pruned.

Fig. 36.—Strong Vine before Third Winter Pruning.

as the terminal bud, and then the cane severed through the next node farther on ; the object of this precaution being, as has been explained in connection with framing spaliers, to assure the formation of only a slight *inverted arch* at the junction of the growths of the old and new extensions.

At the next winter's pruning the vine in Fig. 35 would probably possess half a dozen good canes, and of these the terminal one would be cut to about 15in. or 18in. in length and laid down for further extending the main arm, whilst about two others would be pruned back to spurs of two buds each; the spur nearest to the main stem being at least 10in. out along the arm, whilst the second would be close up to the end of the first year's length of arm.

Fig. 36 shows a much stronger vine, which had about 3ft. of arm laid down the first year, and its third winter pruning (*i.e.*, two years after planting) is indicated in Fig. 37, and four spurs, with an extension rod about 18in. long have been saved. Each of these spurs will give rise to two shoots, and if it be a variety requiring to be rod-pruned, next winter one on each spur will be reserved as a rod to produce the season's fruit, whilst the other will be cut back to a spur to make the necessary shoots for next season's work.

Fig. 37.—Vine in Fig. 36 after Third Winter Pruning.

The vine may now be said to be formed, and the annual pruning consists of suppressing suckers, watershoots, and any superfluous canes along the arm, bending down the canes or rods selected for fruit bearing, and pruning to spurs those most suitably situated for maintaining the shape of the vine and restraining it within bounds. At the same time as this is in progress the terminal cane is continued on from year to year, until such time as the main arm has overlapped the bend of the next vine and made along the trellis one continuous line of main arms furnished with annual growths.

Figs. 38 and 39 illustrate these facts; the first-named being yet in the process of extension towards the next vine, and the latter, having just about linked up the chain of cordon arms, is provided with abundance of rods to use up its very apparent vigor of vegetation. It will be noted that in Fig. 39 the continuation has been pruned to a mere spur only. It may be remarked that should time permit during the summers in which the vine is undergoing its processes of extension, the terminal shoot may be bent down to a

horizontal position whilst it is growing, as this favors the formation of a more perfectly straight main arm than is possible by the use of winter pruning alone.

Fig. 38.—Cazenave Cordon of Moderate Strength Rod-pruned.

Fig. 39.—Cazenave Cordon. A very Strong Vine with Numerous Rods.

Fig. 40.—Horizontal Cordon (Spur-pruned) Overlapping next Vine.

In Fig. 40, a matured design of the spur-pruned Casenave cordon is shown. The overlapping by the terminal of the main arm over the butt of the next vine is also noticeable. This is the type now widely followed by growers

of the Zante currant when submitted to the operation of cincturing or ringing at the period of blossoming, it being found that this vine, under such training, produces abundantly upon spurs of three or four buds.

Fig. 41 gives a general view of trellised vines in the vineyard at Roseworthy Agricultural College. In the foreground Casenave cordons are to be traced, and the distance is filled with Bordelais spaliers. The attention of the reader is incidentally called to the fine cover crop of field peas being grown between the rows of vines to be ploughed down for green manure.

Fig. 41.—Cazenave Cordons in the Foreground ; Bordelais Spaliers in Distance

It may be mentioned, in passing, that cordon-trained grape vines, such as are described herein, may be used for the purpose of shading covered walks and bare walls with equal success to the spalier forms and with much less trouble to the grower. In setting out the plants they should be placed in series of two, three, or four vines, as the height of the structure to be covered may demand, keeping in mind that the greater the number in the series the closer the plants should be set to each other.

Whatever number be selected the pruner should bear in mind that the golden rule of permanently successful training consists in keeping all the fruiting wood grown from any one vine upon a common level, so that the sap may be distributed evenly to all parts.

The following varieties are recommended for trellising, as spaliers or cordons, over ornamental structures and upon high surfaces, because they display much persistency in retaining their spurs or secondary arms in regular order upon the permanent arms :—Black Frontignan, Black Hamburg, Doradillo, Grand Turk, Muscat Gordo Blanco, Muscat Hamburg, Red Prince, Royal Ascot, Sweetwater, Temperano, Wortley Hall, Crystal, Red Frontignan, Zante Currant. Of these the most suitable for forming the higher tiers of any series are Grand Turk, Red Prince, Sweetwater, Royal Ascot, Crystal, and Zante Currant.

EXTRACTS FROM REPORTS BY TRADE COMMISSIONER.

The following are extracts from reports dated London, July 26th, received from the Trade Commissioner :—

INTERNATIONAL ASSOCIATION OF POULTRY INSTRUCTORS AND INVESTIGATORS.

In accordance with instructions from the Honorable the Minister of Agriculture, Adelaide, I attended a Conference that was held in London in connection with the above association. The Conference was opened on July 18th, 1912, and closed on July 24th.

This has been one of the most useful and instructive Conferences it has ever been my pleasure to attend, and I am quite sure that when a detailed report of the whole proceedings is available, it cannot fail to be of interest to the poultry-keepers in South Australia. I strongly recommend all concerned to obtain a copy and very carefully peruse it.

In order that our producers may have some idea of the nature of this report, I give herewith a brief review of the proceedings of the Conference.

It only needs a glance at the list of countries represented to realise the international constitution of the association. The title of the association might lead one to imagine that the whole of the deliberations of the committee would be confined to the scientific side of the industry ; but this was not the case. The committee fully realised that the commercial aspect was just as

worthy of consideration as the scientific, and grasped the fact that the efforts of the scientific men would lose very much of their value unless those interested in the industry commercially also took steps to improve existing methods. Accordingly, the term "Instructors" is meant not only to refer to those actually engaged in teaching how to breed, feed, &c., but also those who are engaged in finding markets and giving instruction as to the best methods of preparing poultry and its products for the markets. It will, no doubt, be gratifying to South Australians to learn that there was not a member present at the Conference who was not well acquainted with what is being done in South Australia in regard to egg-laying competitions, and in a smaller degree scientific research, particularly when it is considered the comparatively small amount of money available for such purposes compared with other countries.

Owing to the world-wide reputation South Australia has attained, due to the magnificent results of the egg-laying competitions, the State itself, and many of its well-known breeders, are known to nearly every member of the Congress. While speaking of egg-laying competitions, I might add that the fact that the competitions in South Australia are carried out under Government supervision adds much to the importance of the wonderful figures we are able to give. The paper prepared by Mr. D. F. Laurie and read by myself, on the "Poultry Industry in Australasia," was much appreciated. One important lesson we have to learn as a result of the information given in the paper, and also of the results of the egg-laying competitions, is that English and foreigners alike are surprised to learn that the poultry industry, in Australia is of so comparatively small commercial value. I gathered from the many remarks which were made that any other country with the natural advantages obtaining in Australia for poultry-keeping would have raised the poultry industry to a leading place among its industries.

Facts given by Dr. Pearl, of America, in regard to the poultry industry in that country are simply astounding; but, as all this information will be given very fully in the general report, it will be unnecessary for me to go into detail now, other than to say that for teaching purposes alone the United States of America Government vote half a million dollars annually; and during the last five years, no less than 20,000 qualified students have passed through the various colleges in the States. When one considers the above facts, it is little wonder the poultry industry is worth annually over 1,000 millions sterling to the country. From an account given by Professor Graham, of Guelph College, Ontario, it will be noticed that the Canadian States are also emulating their neighbors over the border. A very important point to be noticed in connection with the continued advance of the industry in America and Canada is the fact that, though the production is annually increasing, their exports are falling away, and local prices advancing. The secret of this is that in these countries the Governments do not stop when they

have instructed the farmers, &c., how to produce, but have carried their investigations on to commercial lines, and are teaching the people how the poultry and eggs should be prepared and collected for market. They realise that to increase local consumption, the value of poultry as a food should be forcibly brought before the public; that if this propaganda is to have any effect the goods must be of the freshest and most attractive character. Eggs, a fortnight old, that have been exposed to all conditions of weather and methods of collection, packed in any sort of old box and chaff of doubtful character, would not appeal to the American or Canadian public.

The position of the industry in Germany, as explained in the report, is worthy of most careful consideration, particularly in view of the effect it is bound to have on the English markets; though, from a producer's standpoint, there is little to learn, as little progress has been made for many years. The chief point to be observed is the enormous increase in the consumption of fowls and eggs in Germany. There are several reasons for this increase in consumption, amongst others the following may be regarded as the most important:—

1. *Growth of Population.*—In 1880, the total population was 45,000,000; in 1910 it was close upon 65,000,000, and is growing at the rate of about 900,000 per annum.
2. Almost the whole of the additional increase in consumption is in the large manufacturing centres and not in the agricultural districts.
3. Owing to the increase in the general prosperity, and the consequent higher standard of living, as well as the adoption of English and other ideas as to breakfast due to the enormous increase in the number of Germans who now travel.

For many years, at any rate, Germany must be a very large importing country, and accordingly, eggs and poultry from Russia and neighboring countries, which in the past have found a market in England, will be diverted into other channels nearer home, thus leaving England to look for sources of supply elsewhere. I have called attention to the details relating to the countries mentioned to show what may be gathered from the report under review, not only in regard to them, but to other countries represented at the Congress. The main object of the association is to acquire and disseminate information in regard to the poultry industry from and to all parts of the world.

The central office is in London, to which members from all over the world may apply for information on almost any subject appertaining to the poultry industry. The association is governed by a council consisting of members from many different countries. Mr. D. F. Laurie and myself were elected to represent Australia on the council. The condition under which members may join the association, and the very many advantages to be obtained

therefrom, will be found in full detail in the report. This movement is having the practical support of the British Government, and also of the Royal Agricultural Society of Great Britain. Both Lord Lucas and Lord Middleton have taken a very keen personal interest in the proceedings, and it is fully expected that, in addition to the official recognition the association has already received from many foreign Governments, very practical help will be forthcoming.

Owing to the fact that the report has to be compiled in so many languages, it will be some little time before it is available.

Immediately, however, I can obtain a copy I will send one to you. In my opinion, that report will be of the very greatest value to the poultry-keepers throughout the State. I respectfully suggest that such a number of copies be purchased as will allow of the report being placed in all country institutes and other places where they would be available for reference.

FROZEN MUTTON AND LAMB.

Prices are practically the same as last reported. The market continues slow and quiet, and, owing to the strike, which particularly affects the lighter-men, the goods have still to come up by road. In my opinion, this is really the cause of prices remaining the same, *i.e.*, the delay in getting the supplies from the ship to the market.

	Mutton.				Lambs.

Argentine	274,000	..	112,000	

BUTTER.

The market is much the same as when last reported. There has been little business in Colonial butter, but increased supplies have been coming from Siberia. This week has been a record for some long time now for this class of butter. The remarkable feature in the position is the high price of Danish when compared with Siberian. Only this morning I was comparing Siberian with Danish. It was most difficult to decide which was the better of the two butters; and what was my surprise when I was told that there was at least 20s. difference in the cost. This, to my mind, is another instance of the grip that the Danes have on this market. After all, it is a matter of prejudice, and one that I think Australians as a whole should, in their own interests, take some steps to break down. There is still a very considerable quantity of Australian butter in store in London. For the best we are realising from 104s. to 108s., while ordinary fine quality is realising from 98s. to 102s.

CANNED MEATS.

While the very hot weather that has obtained for the last week or two has very materially assisted the sale of such canned goods as salmon and fruits, it has had the contrary effect on the demand for canned meat in tins (6lbs.). The retailers are afraid to open packages of this size on account of their becoming so quickly discolored and going bad. For the very best pack of Argentine corned beef there is a steady demand at from 33s. to 34s. per case, whilst for the ordinary Australian qualities the market is exceedingly slow at from 24s. to 27s. As a matter of fact, if one wanted to clear a big parcel it would be a matter of considering from 20s. to 22s.

A Glimpse of Mount Gambier.

BEE-KEEPING NOTES.

FOUL BROOD.—ITS SYMPTOMS AND TREATMENT.

By T. E. WHITELOW, Inspector of Apiaries.

The wellbeing of the beekeeping industry in South Australia has suffered considerably in the past from the devastating disease known as foul brood. In certain districts apiarists have experienced great difficulty in keeping their bees healthy and vigorous. Recent inspections have shown that this difficulty has been increased by careless beekeepers leaving diseased combs about in exposed positions, thus proving a dangerous source of infection to other bees in the vicinity. In one instance a neglected apiary of 20 hives was discovered, all of which were diseased, and only one solitary hive was inhabited by bees. The remaining 19 hives were being actively robbed by the bees from neighboring apiaries. The onus is on every beekeeper to do his portion of the work of eradicating this disease, and the neglect of a few apiarists cannot be allowed to endanger the livelihood of others who are depending upon honey production as the principal source of income.

The need for active supervision being evident, a vigorous policy has been adopted by the Department of Agriculture. The enforcement of the Foul Brood Among Bees Act, No. 410 of 1887, has had a beneficial effect in removing these sources of contamination. Examinations are being made of the apiaries throughout the State, and where diseased bees are found a careful inspection is made to ascertain whether safe and efficient means are being taken to eradicate the disease in accordance with the clauses of the Act. If no treatment is proceeding, the beekeeper is given a reasonable opportunity to commence action, and, failing this, more stringent methods are adopted to enforce the Act. This policy has the strong support of the beekeeping community throughout the State, and in most instances inspection is appreciated as a safeguard.

The well-informed apiarists are men who are fully aware of the highly infectious character of the disease, and immediately its presence is detected in their apiaries, take drastic measures to stamp it out. They know that one single diseased cell in their hives is as dangerous in its consequences as a lighted match idly thrown down in scrub country during hot, dry weather.

There is always a percentage of beekeepers who are unacquainted with the diseases of bees and the best methods that should be adopted when

treating contagious diseases. Beekeepers have been visited who were unaware of such a disease as foul brood, and yet inspection revealed its presence in their hives. It has therefore been deemed expedient to issue a pamphlet describing the disease, its effects, and the usual methods adopted to ensure its cure. It is not only useless to enforce the provisions of the Act, but it is positively dangerous to do so unless steps are taken to ensure the treatment being thorough, and without infection to neighboring apiaries. A pamphlet on the subject will be an assistance to some beekeepers in effecting expeditious and safe treatment that is likely to be permanent in character.

Foul brood is generally known to be a disease which is not readily cured once it has obtained a strong hold in the apiary, and it is also recognised that drastic treatment must be adopted to effect a cure. The modern system of beekeeping, with its interchangeability of bees, hives, combs, and appliances, materially aids the ready detection and treatment of the disease by competent apiarists. When this system is adopted by beekeepers who do not completely realise the contagious nature of foul brood, then indiscriminate manipulation and exchange of movable parts renders the spread of infection more rapid than with old methods.

THE CAUSE.

The disease is caused by pathogenic micro-organisms attacking the immature larvæ in the brood combs, causing their death and subsequent decomposition. There has been much controversy with regard to these germs, and present-day knowledge concerning them and their relation to disease in bees must always be open to revision as further investigations throw more light on the subject. It is to be regretted that much of the information available is vague, and appears to be based more on conjecture than upon tested truths.

Three organisms are supposed to be pathogenic to bees in connection with foul brood, and are present in different phases of the disease—*bacillus alvei*, Cheshire; *bacillus larvæ*, White and *streptococcus apis*, Maasen.

THE SYMPTOMS.

Two types of foul brood are known, both of which are contagious. One is predisposed to attack the larvæ in the early period of its existence, before it is sealed within the cell. The other variety seems unable to obtain a hold in the intestines of the larvæ at this age, but makes more progress in the tissues of the insect after it has been capped over. The former species is due to the ravages of *bacillus alvei*, and the latter type to *bacillus larvæ*. Both varieties of the pest are known in South Australia; but, so far as investigations have gone, the *bacillus larvæ* type is the most prevalent.

Bees that are weak and ill-cared for present an easy prey to the disease germs. An early symptom is shown by the grubs occupying an abnormal

position in the cell. An unusual restlessness observable in the hive will sometimes lead to the detection of the disease. The larvæ assume a limp, unhealthy appearance, with a yellow tint in place of the customary whiteness of their skin, deepening as the germs multiply, to a color resembling that of coffee. The body diminishes after death by decomposition and evaporation. The decaying mass will stretch slightly in an elastic fashion if an attempt is made to withdraw it from the cell. It eventually dries up, until only a dark-brown scale remains on the lower cell wall. In some instances a glue-like odor is present. Should some of the larvæ escape infection until sealed, the capping will be dark, sunken, with a greasy appearance, and occasionally pierced by an irregularly shaped hole.

Comb Affected with Foul Brood *Bacillus Larvæ*, White.

This type of disease is often found in conjunction with "sour brood," and the germ of the latter disease (*streptococcus apis*) will be found as well as *bacillus alvei*. In such instances the decaying matter will be less elastic, and a sour smell will be present. Bees suffering from sour brood should undergo the same treatment as for foul brood. In the second type of disease the larvæ reach a more mature growth before the disease is much in evidence. The symptoms are easily discernible, the cappings being dark, sunken, greasy looking, and often pierced by a pinhole. Upon opening a cell, the larvæ will be found a decomposing mass, very ropy, having a buff color, and eventually drying to a dark-brown scale, which is difficult to remove. Sometimes on opening a cell only the dried scale will be found. This type of disease

is usually associated with a distinctive odor of glue, which is nearly always in evidence if the disease is of long standing. The odor of foul brood is a somewhat variable quantity, and is probably dependent to some extent upon climatic and atmospheric conditions.

CHILLED BROOD.

Brood often becomes chilled and dies during adverse weather conditions, especially if the hive contains insufficient bees to properly cover the brood nest. Such brood is necessarily foul, but must not be confused with foul brood, which is the generally adopted name of a specific disease. The larvæ in such cases are usually removed by the bees. Their color is a dull grey, afterwards becoming almost black. They can usually be withdrawn from their cells with their structure intact.

SOURCES OF FOUL BROOD INFECTION.

The sources of foul brood infection are—

1. Honey containing the spores of disease.
2. Robbing, by means of which such honey is conveyed from a diseased hive to a healthy one.
3. Feeding bees with honey from diseased hives.
4. Extracting, and returning combs from diseased to healthy hives.
5. Using hives, combs, and appliances which have been in contact with disease without properly disinfecting them.
6. Manipulating from diseased to healthy hives without disinfecting hands and smoker.
7. Using comb foundation made from infected wax which has not been efficiently sterilised.
8. Placing healthy hives on stands previously occupied by diseased hives.
9. Ants are a probable means of disease conveyance from hive to hive.
10. Watering places are also to be considered as likely to become contaminated.

TREATMENT.

The successful treatment of foul brood depends upon the thoroughness of its execution. To "tinker" with the disease is simply to encourage it. To attempt its cure by means of chemicals is usually a waste of time. Measures for disease eradication should be taken prior to a honey flow—preferably at the commencement of the season—so that the bees have a period of plenty before them in which to replenish their hive. Treatment commenced late in the season does not usually give the bees sufficient time to regain their strength before winter. At this period the bees are not inclined to build comb so readily. The tendency to rob is also prevalent at the latter end of the season. Under such circumstances it is advisable to destroy any diseased hives that are weak and unlikely to survive till the following spring. The

others should have their entrances contracted and rendered safe from robbing bees. Treatment is then deferred till the following season.

The treatment which is generally acknowledged to be the best is to remove the bees from their hives and combs, reducing them to practically the condition of a natural swarm. The diseased hive is removed from its stand, and a clean one is put in its place, with a large cloth or piece of paper beneath it. The bees from the diseased hive are brushed, or shaken, from the combs on to the cloth, and allowed to run into the new hive. The latter is fitted with frames having $\frac{1}{2}$ in. starters of comb foundation. The diseased hive and combs are immediately placed where no bees can get to them. The cloth receives any infected droppings, and is gathered up immediately the bees have run in. The ground surrounding the hive should be turned over and dug in.

After three or four days, when the bees have consumed all the honey in their bodies in building comb, they are returned to their old hive, which has, during the interim, been carefully disinfected. This is fitted with wired frames of comb foundation. The small quantity of comb they have built is rendered to wax and sterilised. During the ensuing season a careful watch should be maintained over all hives, to make sure there is no recurrence of the disease. If honey is not coming in freely, the bees should be fed on a syrup composed of sugar and water.

DISINFECTION.

The combs of the diseased hives should have the honey extracted from them, and then melted down and sterilised by prolonged boiling. Such honey is perfectly good for human consumption, but must on no account be fed to bees. The honey extractor should be disinfected after use. It is not advisable to utilise the wax for the making of comb foundation, unless complete sterilisation is assured. The hives and frames should be thoroughly scorched by means of a painter's blow lamp, directing the flame well into the cracks and corners of the hive. If preferred, disinfection can be carried out by well boiling in a strong solution of caustic soda and water. It is advisable to burn the cloths, or quilts, as these are apt to be germ retainers.

Combs containing a fair proportion of healthy larvæ can be placed in the upper storey of a diseased hive, with a queen excluder between the brood box and the storey, to prevent the queen from laying in them. Twenty-one days afterwards all healthy larvæ will have hatched, and the combs can then be removed and rendered down. The hive above which they were placed can then be treated.

MISCELLANEOUS POINTS.

Treatment should not be commenced when there is any likelihood of robbing bees being present.

Too many hives should not be treated at one time, as prolonged disturbance in the apiary will encourage "robbing" and "mixing up."

Early in the season every hive should be carefully examined for signs of foul brood.

Droppings of honey and pieces of comb should not be left about the apiary.

The detection of the disease in its initial stage means an easier cure, and a better chance to completely eradicate it.

RECIPES.

1. Carbolic solution for disinfecting hives and appliances.—Calvert's No. 5 carbolic acid, one part ; water, two parts.

2. Formalin solution for disinfecting hands, &c.—Formalin, one part ; water, 10 parts.

3. Sugar syrup for feeding bees.—Pure cane sugar, 12lbs. ; water, 9pts. ; vinegar, 1oz.

THE FOUL BROOD ACT.

The vital clauses of the Foul Brood Among Bees Act, No. 410 of 1887, are as under :—

1. Every person who shall have in his possession, or under his care, any colony, hive, or swarm of bees affected with foul brood shall forthwith destroy all comb and thoroughly disinfect any box, case, or hive, and any material or thing which shall have been used in connection with bees so infected.

2. Any person who shall, after one week's notice in writing having been served upon him by the inspector or person appointed or authorised under the provisions of the next clause, knowingly fail to observe the foregoing section in any particular, or shall knowingly have on his premises any comb infected with foul brood, shall be guilty of an offence under this Act, punishable on summary conviction by a penalty of not less than five shillings or more than ten pounds.

TO INQUIRERS.

Letters having reference to apicultural matters should be addressed to the Inspector of Apiaries, Department of Agriculture, Adelaide.

POULTRY NOTES.

By D. F. LAURIE, Poultry Expert and Lecturer.

OPERATIONS FOR SEPTEMBER.

Hatching should be in full swing this month, so that by the middle of October, in the north, and the end of that month in late districts, such as the hills and South-East, all chickens required should have been hatched. Ducklings and turkeys can be hatched until November. Late-hatched chickens do not pay. They are from eggs laid by hens at practically the end of the season, and at a time when the male birds are generally lacking vigour. Late-hatched chickens are handicapped by such a start in life, and rarely make fine well-grown adults. They feather badly and are prone to diseases. The cockerels mature slowly, and are only ready for market when the supply is plentiful. The cost of rearing and fattening late-hatched chickens is much greater than in the case of those hatched early. The pullets do not lay until the spring, as they are not matured until the cold weather; often they have not the stamina necessary for egg-production in severe weather.

Sale of Chickens.—Those who have neglected to hatch the required number of chickens can still purchase chickens from many reliable breeders. The trade in day-old (just hatched) chickens is growing. Day-old chickens can travel with safety on a two days' journey. When a month old or older they cannot stand long journeys so well.

The Demand for Table Chickens and Ducklings will be very good this year. Hatch as many as you can, feed well, and lose no time in getting them ready for an early market. Most breeders keep back their supplies for the Christmas markets until within a week of Christmas Day. This is a great mistake. It was all right in the old days, but cold storage has altered trade methods completely. The trade in dressed poultry has increased enormously, and dealers must buy beforehand in order to accumulate sufficient stocks to meet demands. These stocks are held in cold storage. From November to the middle of December the market is generally active, and prices are good. Time your chickens and ducklings for delivery in prime condition at about this period.

Eggs.—The approach of the general laying season of farm fowls is bringing down the price of eggs. As the warm weather approaches the quality of the

ordinary market egg does not improve. Stale and rotten eggs cause a loss to the State of over £50,000 worth annually. Shut up your male birds and market only infertile eggs, and thus help to avert some of this scandalous loss. Wash the shells of all dirty eggs. It is poor business to sell any unattractive produce. Eggs with dirty shells are not attractive—they are decidedly repulsive. The dirt and manure on the shells of such eggs are swarming with micro-organisms. These may include filth and disease germs, and may endanger human life. Quality in produce is the keynote to success. The French and Danish eggs bring the highest prices on the English markets, because the quality can be depended upon and the shells are always clean. All the eggs from the Government poultry stations forwarded for sale in Adelaide, are infertile—their shells are clean, and they are graded into two sizes. Large eggs realise one penny above market price. These eggs are in great demand. These methods are adopted as profitable business methods. They pay well.

Greenfood.—Do not delay any longer in making provision for a summer supply. Lucerne can be sown now in any district, but the ground must be well prepared, and should be well manured. Lucerne is the best of all green foods for poultry. With good cultivation it will do well on a limited water supply. Silver beet is an excellent summer fodder. In rich soil and with a fair amount of water, a great and continued yield can be obtained from a small area. Maize—90-day, and some of the newer fodder varieties—will give a big yield of excellent green food. It should be sown thickly for successive crops, and cut young. There is no poisonous glucoside, as is sometimes the case with sorghum, which is not so good for poultry. In late districts, and where the rainfall is good, it is not too late to sow rape. Kail plants can still be set out.

Vermin.—With the advent of warm weather the various parasites of poultry (lice, ticks, &c.) will evince increasing activity, and if unchecked will produce swarms of young. The majority of losses among poultry, generally attributed to diseases, are in reality due to the depredations of vermin. Ticks, especially, should be eradicated. Read the article now appearing in this issue of the *Journal* on the poultry tick, and look up the previous numbers. Use kerosine emulsion freely on the poultry houses, after first cleaning out all filth and rubbish. Dispense with any unnecessary woodwork. To 9galls. of boiling soapsuds add 1gall. of kerosine. Churn and mix thoroughly and apply boiling hot—saturate all woodwork and flood cracks. Infested birds may be dipped in the above mixture, at a temperature not exceeding 100 degrees F. Choose a fine day; immerse the bird and thoroughly saturate the plumage; squeeze the feathers dry, and place the birds in a warm coop facing the sun, where they can dry their feathers.

The Chickens must be kept growing. If you do not feed them well, upon nourishing food, you cannot reasonably expect them to become profitable

adults. It is the utmost folly to attempt to rear stock on starvation rations. The science of feeding is a rational one, yet it is strangely disregarded by those who should know. Give as much variety of food as you can. Monotony in the composition of the food rations can only have one result—stagnation and general unthriftiness. The most recent scientific conclusions, founded upon carefully carried out experiments, prove conclusively that no one food contains the necessary constituents for all the functions of life. Feed the young stock on mixed cracked grains, and after they are a month or so old, give at least one meal a day of mash, to which must be added some animal food. Give plenty of cut greenfood, which will supply the mineral salts so very essential. Green fodders vary in their mineral content, both as to quantity and nature; therefore, give as much variety as you can. Provide sharp sand and grit to aid the mechanical processes of digestion.

Ducklings, like chickens, must never receive a check in their growth—they must be kept well fed. Give them variety of food, and remember that animal food is absolutely essential. Of cut green food and grit they can consume astonishing quantities. Market ducklings should be forced on so as to be ready at from eight to ten weeks from the shell. Keep a full supply of clean fresh water at all times, day and night. Thirsty ducklings will die like flies as soon as they have access to water, of which they drink too much. Therefore, never allow them to want for fresh clean water. House them in clean, dry sheds, using plenty of clean straw.

Goslings are generally sent to market in miserably poor condition. True, the goose is a grazing bird, but as a rule round the homestead there are numerous horses, cattle, and poultry, which eat all the available grass, and the young goslings suffer. Feed at least once a day on bran and pollard, or ground wheat. During the last fortnight give them all they can eat and send them down fat to market. Sell to a reliable dealer and it will pay you. Sell goslings, do not sell off your breeding stock—they are tough and not of very fine flavor.

Turkeys should be bred in large fox-proof enclosures. There is a splendid market, and supplies are yearly decreasing. Turkey-breeding should become a most valuable branch of the industry; the profits are great, and the prospects for continued high prices are most encouraging. Market only the well grown, thoroughly fat, young birds, not exceeding six months old. Introduce some American Bronze stock, so that you can grow large birds. Turkeys are sold at per pound—therefore, the large varieties are the most profitable.

Incubators should be scrubbed clean after each hatch, and then should be disinfected with the fumes of burning sulphur. Supply a new wick to the lamp each hatch. Follow the maker's directions for working.

Sitting Hens and Turkeys should be well dusted with a good insect powder. Examine the nest and see that it is also free from vermin. Many losses and disappointments are due to vermin.

Sun Shades should be provided for the stock. They can be made of a permanent or of a temporary nature. Serviceable shades may be constructed of split wheat bags stretched over a low framework and whitewashed. Shelters may be made of straw ; others more lasting may be made of galvanized iron. Iron structures of all sorts should receive two coats of thick whitewash ; this will materially reduce the temperature.

Poultry Houses may be covered with a good layer of straw, held in place by strips of wire netting.

POINTERS.

Don't crowd your chickens and ducklings. Give them room and plenty of fresh air. Keep them out of draughts, but let them have sunlight.

Don't use inferior foods. The so-called fowl's wheat should have no place on a properly conducted poultry farm. Food of proper nature will do good—rubbish contains little or no nutriment.

Don't expect satisfactory egg yields from old hens. The average hen does not lay a profitable number of eggs after the second season.

Don't neglect to keep all yards and houses clean. Disinfect the water vessels, and see that clean, fresh water is always in them.

Don't expect lively, vigorous chickens and ducklings unless your breeding stock is healthy and properly housed and fed.

Don't make the mistake of trying how many breeds and varieties you can accumulate. Remember that the most successful poultry breeders confine their attention to one breed or variety.

Don't buy so-called cheap stock, eggs, or appliances. First-class utility poultry cost more money than do exhibition fowls. From such you can expect definite and uniformly good results. From cheap rubbish you may rely upon inferior and disappointing results.

Don't blame the business because your methods are faulty. House your stock so that cats, &c., do not destroy your season's work. Keep the doors closed at night, and do not trust to luck. One might write a chapter upon this subject.

Don't keep mongrel stock. The advance of knowledge in this 20th century makes this point clear. In utility breeding you start with pure bred stock, and then develop the utility characters until you breed these characters pure. Learn this fact and you will be on the road to success.

Don't fail to write to the Poultry Expert if you are in trouble or require any information.

EGG-LAYING COMPETITIONS.

TWELVE MONTHS' TEST.

ROSEWORTHY.

[Started April 1st, 1912, and to terminate March 31st, 1913.]

Competitor.	Eggs Laid for Month ended Aug. 31st.	Total Eggs Laid from April 1st, 1912, to Aug. 31st, 1912.

NOTES ON EGG-LAYING COMPETITIONS.

ROSEWORTHY AND KYBYBOLITE POULTRY STATIONS.

The more favorable weather recently experienced has resulted in all-round general improvement and consistent laying. The eggs were weighed on July 31st, in conformity with the regulations. A number of pens failed to reach the required weight of 24ozs. to the dozen, and are, therefore, debarred from competing for a prize.

The pens which failed are as follows:—

Roseworthy.—Section I.—Pens 10, 37, 42, 50; Section II.—Pens 85, 86, 89, 90, 94, 97, 98, 105; Section III.—Pens 4 and 8.

Kybybolite.—Section I.—All reached the required weight. Section II.—Pen 33 failed. Space does not admit of further dissection of the results. I may state, however, that an analysis of last year's results in Section I. show that it is a mistake to think that hens laying small eggs lay more than those laying fairly large eggs.

ROSEWORTHY.

The Superintendent reports:—The general health of the birds was good. During the month one bird had a mild attack of chicken pox and one an attack of roup; both birds are isolated and under treatment; they will be restored to their respective pens in a day or two. Two deaths occurred during the month, one White Leghorn in Section I., also the bird which was sent to replace same. The upward tendency in the laying is most gratifying, as it has been most consistent and places the averages, both individual and per pen, well above those up to and including the same period last year. With the advent of a few warm days the heavy breeds kept up their reputation for broodiness; 23 have paid a visit to the pens set apart for that purpose. Section I. also contributed two hens to the broody pens. The weekly scores will show that moulting has finished; this is a pleasing feature, as the moult has been of a very extended character this year. The scores for the month will approximate 15,000 eggs, compared with 10,000 for the month of July. Apart from the improving weekly averages for each pen, the feature of the laying has been the consistent good work put in by the leading pen, which is going strong for a new record, provided they can hold out. The weather during the month has been of a mild character. The average maximum was 64·9, the highest reading 75·6; the average minimum 39·38, the lowest reading 28·1. We have had almost a daily visitation of wind, which was chiefly from the south-west. Rain fell on eight days; points registered, from 1 to 164, total registration 2·51.

KYBYBOLITE.

The Superintendent reports:—The general health of the birds has been good, no deaths nor any cases of sickness occurring. Two birds in Section II. had to be removed from their pens owing to broodiness. The laying during the latter part of the month has shown marked improvement on last month, although wind was registered on 20 days. Several pens were shut up and did not lay for a few days during the month, but they have now commenced and are doing good work. The leading pen is laying consistently and will take a lot of catching, unless something unforeseen happens. The minimum temperature was 29°, and the maximum of 67°.

1913-14 LAYING COMPETITIONS.

The Hon. Minister of Agriculture has authorised tests to begin on April 1st, 1913, at the poultry stations, Roseworthy and Kybybolite. There will be three sections in each test, and prizes of £10, £5, £3, £2, £1 in each section; total prize-money £126. The sections are—Section I., light breeds; Section II., heavy breeds; Section III., any breed. The latter section is confined to persons engaged in pastoral, farming, market gardening, and fruit-growing pursuits, who reside on land they occupy as tenants or as freeholders. Further particulars may be had on application.

D. F. LAURIE, Poultry Expert and Lecturer.

JONATHAN APPLE.

A. Vaughan, Govt. Photolitho

APPLE—JONATHAN.

FRUIT.

Size—Medium, fair samples averaging 2½ in. long by 2½ in. wide. *Shape*—Slightly and evenly conical. *Color of skin*—Much covered with bright red, sometimes splashed and streaked with darker red, otherwise rich bright golden yellow, the whole surface strewn with small indistinct russet dots. *Eye*—Closed, with sepals short and slightly flat convergent, set in a basin of moderate depth, narrow, regular, and slightly ribbed on the sides. This cavity is usually lightly stained with red, but when grown in shade is clear yellow. *Stamens*—Median position in funnel-shaped tube. *Stalk*—About ¾ in. long, slender, and clubbed at outer end. It is inserted in a round, even, fairly deep cone-shaped basin, which is usually lined with smooth brown russet, which passes off into irregular russet streaks as it ascends up the walls of the basin. *Flesh*—Pale yellow, moderately tender and juicy, possessing a sweet, spicy flavor. *Seed Cells*—Obovate, axile, very symmetrical.

TREE.

Habit—Erect when young, but, owing to the shoots being slender the tree becomes willowy and spreading or rounded after fruiting begins. The lateral shoots are long, divergent, slender, and downy, causing the bark to assume a peculiarly distinct greyish tint, with sparsely scattered round dots. The buds near the base of the lateral are not well developed. If left unpruned the buds on these laterals spur well and soon bear fruit. The leaders should be pruned fairly hard for several years after planting to keep the tree erect, but the laterals merely spaced and left unpruned until after they have fruited. Tree not very subject to fungus diseases. *Climatic and soil conditions*—Thrives and yields best flavored fruits in cool localities and fairly rich, damp soils, such as are found in Mount Lofty Ranges and the South-East, and to a lesser degree in Barossa and Wirrabara Ranges of South Australia. *Value*—Probably the best apple for export trade and local consumption in its season. It is not very liable to “bitter pit,” but in cold storage develops a dark skin spot. It is ready for shipping in March; local season April-June. *Origin*—Kingston, New York, U.S.A., named after Jonathan Hasbrouck, who first brought it into notice.

ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board was held on Wednesday, August 14th, there being present Mr. A. M. Dawkins (Chairman), Col. Rowell, Messrs. C. J. Valentine, C. J. Tuckwell, C. E. Birks, G. F. Cleland, J. Miller, F. Coleman, and G. R. Laffer, Professor Lowrie, Professor Perkins, and G. G. Nicholls (Secretary).

RAILWAY ADVICE NOTICES.

The Secretary reported that the Railways Commissioner had sent to the various stationmasters a circular intimating that consignees could arrange with them where telegraphic communication existed to forward collect telegrams notifying the arrival of goods. If telegraphic advice should not be asked for, the usual advice note must be posted immediately upon the arrival of the goods.

WILD DOG SCALPS.

A request was received from the Hookina Branch that the opinion of other Branches might be obtained regarding a proposal to impose a tax of 1s. a square mile on land outside vermin-fenced areas, and 6d. a square mile on that inside, for the purpose of raising funds to pay for the scalps of wild dogs. It was decided to accede to the request.

EXPERIMENTAL ORCHARD.

Professor Lowrie suggested that, if possible, arrangements should be made to enable the delegates to the Congress to inspect the experimental orchard at Coromandel Valley, which, while it was probably the best bit of work of the kind in Australia, was scarcely known. The orchard was well laid out, and its value to the State would increase with each succeeding year. Numerous exceedingly useful experiments were being conducted, and he was confident the results recorded would be of the utmost help to the fruit industry. It was worthy of note that practically all, if not all, the tests proposed by Mr. McAlpine in connection with his investigations into bitter pit in apples were comprehended in the experiments before Mr. McAlpine's plans were made known. That he regarded as a high compliment to the man who had been responsible for the scheme laid down and in course of evolution. The Board agreed to recommend the Minister of Agriculture to make the requisite arrangements for members of the Congress to visit the orchard. It was also decided that the Board should pay a visit of inspection later in the season.

TAINT OF WEEDS IN MILK.

Mr. Tuckwell said that it was well known to dairymen that the taint in milk produced through the cows eating weeds could be almost entirely eliminated by dissolving in hot water in the milk pail (using the smallest quantity of water possible) as much saltpetre as would go on a threepenny bit, and then milking into the pail. There were two kinds of saltpetre, however, viz., nitrate of potash and nitrate of soda. The former was the proper one to use. It was easy to distinguish between the two, as nitrate of potash, when placed on live coals, produced a violet flame, whereas nitrate of soda gave forth a yellow flame.

LOUSY SHEEP.

Mr. C. E. Birks said that it was generally considered in his district that lice in sheep had been introduced through the medium of Shropshire rams purchased at the Adelaide sales. The matter had been discussed by the Port Pirie Branch of the Bureau, which had determined to strongly urge upon the authorities the necessity for stringent measures being taken to prevent the spread of lice in the manner indicated. At present dozens of rams were losing their wool. The Branch thought that something should be done to compel the owners to dip their rams before they were offered for sale. Mr. Valentine pointed out that that could be done now if the sheep were discovered to be infested with lice. Professor Lowrie thought that would affect the sales, as no man would like to dip his sheep within a month before the sale. In New Zealand there were public dips at the saleyards, and an inspector examined all store sheep. When animals were found to be infested the auctioneer declared prior to offering them that they must be dipped before they left the yards. It was decided that Professor Lowrie, Messrs. T. H. Williams (Chief Inspector of Stock), Birks, and Valentine should go into the question, and take whatever action might be deemed advisable.

SOUTH AUSTRALIAN FLOUR.

Attention was directed to the bread-making qualities of South Australian flour by Mr. Coleman, who displayed a quantity of compact and attractive loaves of bread made by an Adelaide baker from South Australian flour. Mr. Coleman explained that when the members of a leading firm of English confectioners were in Sydney some time ago they poo-pooed the idea that Australian straight flour could make a good bread, and contended that to obtain the best results it would have to be blended with flour from elsewhere. Mr. Coleman said that the baker referred to urged that something should be done in the direction of establishing a school of bakery in South Australia. It was decided to ask the Minister to direct the attention of the Trade Commissioner to the fact that some prejudice existed in regard to South Australian flour in England for baking unblended, so that some steps might be taken to demonstrate the excellence of the loaf made from it.

IMPORT DUTY ON FERTILISERS.

Mr. Coleman said the Saddleworth Branch of the Bureau had recently resolved to vigorously oppose the proposed duty on imported superphosphate. He hoped that the Government would take effective action in that direction. The farmers were not so favorably situated in respect to duties as those engaged in most other industries, in that they could not pass them on. The Secretary said the subject had already been brought under the notice of the Minister, who had taken action at the Conference of Ministers in Sydney recently.

EXPORT OF FRUIT.

Professor Lowrie stated that he had received the following letter from the Under Secretary for Agriculture in New South Wales :—" With reference to the resolution passed at the Conference of Ministers of Agriculture in Sydney, to the effect that the shipping companies be urged to provide separate chambers for the particular quality of fruit that might be shipped from each Australian port, and that, after stowage, such chamber be kept closed from the commencement to the end of the voyage, I have to inform you that such resolution has been placed before the principal oversea companies, and their replies indicate that, while the advantages contained in the suggestion are recognised, and their past endeavors have been to give effect to it so far as possible, they are unable to comply wholly with the request. If, however, each State will guarantee to fill each chamber set apart, or pay for any space which may be left vacant, the request will be reconsidered." This communication had been forwarded to the Government Horticultural Expert (Mr. G. Quinn), who had reported :—

" I am of the opinion that the attitude assumed by the shipping companies in respect to the allotment and filling of the insulated space in their ships is the only one that could possibly be taken up in respect to the resolution placed before them. I take it the object sought in such a resolution is to prevent fluctuations of temperature in any cool chamber after the first fruit is placed in it and the air has been brought down to the degree considered to be necessary to the preservation of the fruit. There appear to be difficulties in providing in each ship chambers for the respective States which shall have a capacity equal to that number of cases the shippers are able to supply at the port of call of each such State. If the export trade throughout the Commonwealth were thoroughly organised, these difficulties might disappear, and the proposal come rapidly within the range of adoption into practice. That desirable state of affairs, however, does not exist, and is not likely to eventuate for some time to come. It would be a step in the direction of achieving the object sought in the resolution if all fruit were cooled down before being taken into chambers. It is only reasonable to assume that, on the score of economy in working their refrigerating machinery alone, the shipping companies have so far as practicable completely filled the chambers as they

proceeded with the loading from port to port. Even if the freights were the same for the space from the last port as from the first, I can see no reason for a different action on their part.

"If the shipping companies insisted on all fruit being cooled prior to being received on board the fluctuations of the temperatures in the holds would be minimised, as well as a saving made of the energy now imposed upon the ship's refrigerating machinery. This pre-cooling might involve some hardship to the shippers at first, until the system became established; but I am of the opinion that the efforts to bring the fruit to the wharf a couple of days earlier, and the cost of the cooling, would be amply repaid in the general security vouchsafed to the whole cargo of fruit through its operation. Fruit now travels at times to the ship's side on trucks, or on other vehicles, through air temperatures varying from 90° to 100° F. in the shade, and at the time of going aboard the contents of many of the cases must retain degrees of heat closely approximating to these figures, with results disastrous alike to that and to the fruit previously stored therein. It was largely with a view to securing the elimination of its latent heat before stowage took place that I have strenuously sought to insist on fruit being at least 24 hours at the appointed places for examination under the Commerce Act, and secured as 'appointed places' premises where proper accommodation for cooling the fruit existed. The shippers, however, have all along resisted this object, mainly because a charge of 2d. per case has been made for this service—although, if they desired it, storage for a week, which is more than ample time to cool down their produce, has been offered for this amount. It is all very well to ask the shipping companies to adopt additional precautions to safeguard the carriage of fruit, but the shippers must also do their share in assisting to secure their produce against depreciation. Up to the present they have not possessed themselves of the advantages which are made available to them, in this State at any rate, of bringing their fruit to the ship's side in a condition which all authorities on refrigeration consider essential to achieving the most successful storage. In regard to the resolution, I respectfully advance the opinion that, as the States appear to be no longer empowered to impose restrictions over exports, the Commonwealth Government might be approached with a view to making pre-cooling of fresh fruit for at least 48 hours prior to its being exported a compulsory rule. There may be, and doubtless is, some laxity of precaution on the part of the shipping companies, but I am in a position to assert that the shippers have not done all that they could to help in making it possible for their fruit to be carried in the best condition."

Professor Lowrie said he had brought the two communications under the notice of the Board because the matter dealt with was one about which he knew very little, and it had occurred to him that the Minister of Agriculture would be grateful for any informative opinions which members might

have to put forward. Mr. G. R. Laffer fully agreed with Mr. Quinn that it was unreasonable to expect the shipping companies to do everything, when the shippers neglected the very things in which they might help them. Twelve months ago a very large proportion of the fruit sent from South Australia had not the slightest chance of reaching its destination in good order, for the reason that it was put into the chambers at Port Adelaide in almost a red-hot condition. Col. Rowell considered that the great fault was in the management of the refrigerators on the steamers. Some time ago he sent to England two lots of similar fruit (which had been pre-cooled) by different steamers. One consignment arrived in excellent condition; the other was wasted and yellow. Mr. Laffer largely blamed the Produce Department and the Chief Inspector. He had seen at the Port Adelaide Depot fruit placed in such a position that it was bound to be detrimentally affected. He had always paid for cool storage here, but when the State authorities repudiated all responsibility in regard to the fruit placed in the department's cool chambers, how could they ask the shipping companies to put tell-tale thermometers in their holds? Mr. Quinn was quite right relatively to the necessity for pre-cooling, and there was no doubt that if stuff was put into a hold in a heated state it must have a prejudicial effect upon the fruit already there. He contended that in the case of fruit to be held at the Depot for a week, the management should be empowered to put it into the cool stores. Col. Rowell pointed out that during the season just closed one line of steamers had not landed a single case of bad fruit, and all of this had passed through the Depot. Mr. Laffer said the Government had created a monopoly so far as cool storage was concerned, and it was a disgrace therefore that it declined to hold itself responsible for maintaining the temperature at a proper standard. After further discussion, it was decided that Professor Lowrie, Col. Rowell, and Mr. Laffer should inquire into the whole matter, and present a report and recommendation at the next meeting of the Board.

LIFE MEMBERS.

A number of names of members of the Bureau were submitted for approval by the Board as life members, and the following gentlemen were duly approved:—Carrieton—J. W. Bock; Mount Pleasant—W. Lyddon; Minlaton—S. Vanstone; Arthurton—T. H. Hawke, T. B. Wicks; Strathalbyn—M. Rankine, J.P., J. Cheriton; Redhill—D. Steele, F. Wheaton; Stockport—J. Smith, D. G. Stribling, J. Murray; Wilmington—W. Slee, A. H. Noll, R. G. S. Payne.

NEW BRANCH AT CLANFIELD.

The formation of a Branch at Clanfield was approved, with the following gentlemen as members:—Messrs. E. A. Pavy, E. H. Milne, D. A. Orwell, W. Paul, A. Clutterbuck, D. A. Orwell, jun., P. Nelson, J. Nelson, W. G. Cowley, G. F. Heaven, A. E. Heaven, A. Richards, L. Gilbertson, G. Watson, F. Franklin, W. Queale.

NEW MEMBERS.

Maitland—E. A. Smith ; Mount Barker—F. von Doussa, G. Milne, R. Hollamby ; Yabmana—B. Howell, H. Schuman, F. Schermiers ; Shannon—H. Roediger ; Coorabie—G. A. Stott, C. J. Wheadon, H. Coppins ; Parilla Well—R. Filby, F. Nordhaussen, A. Nordhaussen ; Clare—W. J. Maynard, S. Pascoc, F. J. Knappstein, R. Hunter ; Monteith—J. Fletcher, W. J. McCulloch, G. Fraser ; Mount Remarkable—W. Smith, jun., E. M. Willington, E. B. Andrews ; Coonalpyn—J. J. Cronin ; Crystal Brook—C. H. Seidel ; Elbow Hill—C. G. Jacobs ; Miltalie—C. E. Searle, R. J. Searle ; Mallala—H. Jury, E. Penfold ; Longwood—H. Winter ; Mount Bryan—G. L. Nut ; Wirrega—H. G. Stevens ; Coomooroo—A. H. Cooke ; Butler—R. T. Harrowfield ; Parrakie—A. S. Johncock, T. Willis, M. J. Cooney, T. Lewis, J. A. Ferme, S. R. Good, A. G. Heinzel ; Penola—T. Yeates ; Mount Barker—C. Alexander, F. Adams ; Gladstone—H. Reynolds, J. Page ; Lyndoch—G. W. Warren ; Freeling—C. H. Schultz, J. H. Gramp, J. Kuhlmann, A. Elix ; Mount Bryan—E. Thomas ; Yadnarie—B. B. Crosby, A. A. Edwards, S. H. Pearce ; Narrung—G. R. Goode, F. E. McNicol, T. E. Barker ; Moorlands—W. Maishman ; Georgetown—C. Read ; Angaston—F. Pearson ; Pinnaroo—G. Fuller, M. Beckwith ; Minlaton—S. F. Hoyle, A. Washington, D. McKenzie, H. A. Chester, A. D. McKenzie, P. W. Griffiths, J. Williams, H. Mumford ; Hooper—J. Boyce ; Burra—E. B. Merkel, A. Brown, J. Wise, S. Burns ; Dowlingville—W. Whittaker ; Coonalpyn—M. S. C. Good ; Mount Gambier—R. Fowler, P. Krummell ; Morgan—O. Hausler, E. Gilgen ; Kybybolite—A. H. Bradley, jun. ; Crystal Brook—A. McDonald, J. H. Shearer, H. Growden ; Hooper—R. J. Chenoweth, B. Chenoweth ; Stockport—E. Weckert ; Maitland—R. Bowey, A. Bentley ; Woodside—G. J. Sampson ; Clare—G. Gerteau, H. A. Hanna, R. Stuart, E. Nancarrow.

THE WHEAT MARKET.

During the greater part of last month the wheat market was dull and inactive. The extensive damage to the English crops through excessive moisture, and less favorable reports received from other countries, however, caused the London market to firm, a result which was at once reflected locally.

Commenting on the wheat position, *Beerbohm's Evening Corn Trade List* of August 2nd states :—"Shipments last week were only moderate, but the proportion destined for the United Kingdom was again very large, and the quantity now actually afloat, added to only small exports from the United States and Canada during the next two weeks, ensure ample supplies for the next four or five weeks, so far as the United Kingdom is concerned. For the Continent, however, the afloat figures have been rapidly decreasing, and it is therefore all the more necessary that there should be a speedy change to fine weather, so that native wheat may be available.

"Latest crop reports from France are less favorable, although it is still generally believed that the yield will be equal to that of 1911, but with the quality inferior to last year's, and as reserves of old wheat are very small, an import of 3,000,000 quarters to 4,000,000 quarters of foreign wheat will be necessary, the greater portion of which will probably be bought in the latter part of the season. There is not much change to note in crop prospects so far as other importing countries are concerned, excepting that the Hungarian crop is now estimated at nearly 1,000,000 quarters smaller than last year. From Russia the latest advices are favorable, and a yield above the average is expected in the greater part of the country.

"The weather in America and Canada during July has, on the whole, been very favorable for spring wheat, and instead of the condition deteriorating considerably in the United States, as was the case last year, prospects at the present time are reported to be distinctly better than a month ago. Some reports of black rust have been cabled over this week, but, judging from the course of the American option markets, little importance has been attached to same. What is now wanted is three or four weeks of fine warm weather to bring the crops to maturity, and to ensure good quality ; if such should prove to be the case America may be in a position to export much more wheat in the season just commenced than was expected a month or so ago. The *Cincinnati Price Current* now estimates the probable yield at about 700,000,000 bushels, or 70,000,000bush. more than indicated by the July Bureau report, and 80,000,000bush. larger than last year's final official figure, but which estimate is believed to have been too small. The winter wheat harvest was distinctly later than last year, especially in those States which have the largest yields, so that shipments in quantity, in all probability, will also be later. In August last year the United States shipped quite freely. Fair quantities of American winter wheat have been sold to Liverpool and also to the Continent."

STEAMER FREIGHTS.—(September 1st)—Steamers from South Australia to United Kingdom-Continent, full cargo rates, old wheat, 28s. 9d. per ton (9½d. per bush.); new crop, 33s. per ton (10½d. per bush.). Parcels, Port Adelaide to London, Liverpool or Continent, 17s. 6d. per ton (5½d. per bush.); Port Adelaide to Melbourne, 8s. per ton (2½d. per bush.); to Sydney, 10s. 6d. per ton (3½d. per bush.)

SALER FREIGHTS.—From South Australia to United Kingdom-Continent (Dec.-Jan.), 31s. 3d. per ton (10d. per bush.); old wheat, 28s. 9d. per ton (9½d. per bush.); to South Africa (Sept.-Oct.), 22s. 6d. per ton (7½d. per bush.); new season, 25s. per ton (8d. per bush.).

DAIRY AND FARM PRODUCE MARKETS.

The General Manager of the Produce Export Department reports on August 31st :—
BUTTER.

It is satisfactory to note that the supply of cream is increasing steadily, and is of good quality. Butter is in great demand, but prices are much lower than at the end of last month. Present quotations are :—Superfine, 1s. 3d. per pound ; pure creamery, 1s. 2d. per pound.

A. W. Sandford & Co., Limited, report on September 1st :—

BUTTER.—Further fine rains have been experienced in most districts, with specially useful falls over the northern agricultural areas. Quantities of cream and butter have, therefore, further increased, and values, as anticipated, have eased. Best factory and creamery butter, fresh in prints, sold at from 1s. 1½d. to 1s. 3d. per pound ; choice separators and dairies, 1s. 0½d. to 1s. 1½d. ; store and collectors', 10½d. to 11½d.

EGGS.—The forwardings showed a substantial improvement, and in consequence the seasonable lowering in price occurred. Owing, however, to the oversea orders now coming on to this market, coupled with extensive local trade, rates have steadied to 9½d. per dozen.

CHEESE.—The month's turnover has been large and fair prices have ruled, though, with lower quotations from the eastern States, values are not as high as they were. Quotations—New make, for large to loaf, 7½d. to 8d. per pound ; matured, up to 10½d.

BACON AND HAMS.—Considerably higher prices were experienced during August, following on the firming that was recorded at the end of July. Best factory cured sides brought 10d. to 10½d. per pound ; hams 11d. to 11½d.

HONEY.—As it is late in the season very few lots of quality have come along. Prime clear extracted brought 3½d. ; second grades, 2d. to 2½d. ; beeswax is very saleable at 1s. 2d.

ALMONDS.—Values throughout the month have been stationary, and, as it is between seasons, there are only odd lots being forwarded. Brandis, 5½d. ; mixed soft-shell, 5d. ; kernels, 1s. 2½d.

LIVE POULTRY.—The catalogues for August have been heavy, but owing to active local demand, combined with oversea buyers operating, very satisfactory rates have ruled. Good table roosters realised from 3s. 6d. to 3s. 10d. each ; plump cockerels, 2s. 6d. to 3s. ; hens and light cockerels, 2s. to 2s. 6d. ; ducks, 2s. 6d. to 3s. 6d. ; geese, 4s. to 5s. ; pigeons, 8d. ; turkeys, from 7½d. to 10½d. per pound live weight for fair to prime table sorts.

CARCASS MEAT.—Very high figures have been ruling, the supply being not nearly equal to demand, so that buyers bid keenly for all submitted. Bright handy size shop porkers brought from 6d. to 7d. per pound ; good baconers, 5½d. to 6½d. ; heavy and poor stuff, 2d. to 3d. ; nice dairy veal, 3d. to 4d. ; fair quality, 1½d. to 2½d.

POTATOES AND ONIONS.—The market throughout the Commonwealth for both potatoes and onions has been bare, and values have in consequence risen to a figure that has somewhat checked consumption. Present quotations are—Potatoes, £10 10s. to £11 per ton on trucks, Gambier ; onions, £19 to £20 per ton on trucks Gambier.

RAINFALL TABLE.

The following table shows the rainfall for August, 1912, at the undermentioned stations, also the average total rainfall for the first eight months in the year, and the total for the eight months of 1912 and 1911 respectively:—

Station.	For August, 1912.	Average To End August.	To End August, 1912.	To End August, 1911.	Station.	For August, 1912.	Average To End August.	To End August, 1912.	To End August, 1911.

A Shire Sire at Sandringham.

FARM ANIMALS.

HEREDITARY UNSOUNDNESS.

By J. F. McEACHRAN, M.R.C.V.S., Government Veterinary Surgeon.

Amongst horseowners it is recognised that a sound horse is better than an unsound one, the sound animal being one that is capable of doing everyday work, and not being affected with anything that is at all likely to produce lameness, and thus interfere with its usefulness. It is quite unnecessary to go into the question of heredity. Suffice it to say that certain diseases affecting horses are laid down as hereditary unsoundnesses, and in the existing regulations dealing with the veterinary examination of stallions for the Government certificate of soundness the following list of hereditary unsoundnesses is prescribed:—Sidebone, ringbone, bone spavin, thoroughpin, bog spavin, bursal enlargement and curb, roaring, shivering, cataract, and osteo porosis.

Stockmen are already aware of the conditions governing the examination of horses for the Government certificate, and the reports of the results of the examinations since the inauguration of the system have been published. The report for the year ended August 31st, 1912, is now in course of preparation.

That a large percentage of our horse stock are affected with certain hereditary unsoundnesses is now an established fact, and it is well that the more prevalent of these diseases should be described, so that owners themselves may be able to recognise them. Breeders should be very particular only to breed from absolutely sound stock.

In South Australia the unsoundnesses met with, in order of frequency, are as follows:—Sidebone, ringbone, bone spavin, thoroughpin, and curb.

SIDEBONE.

By far the commonest unsoundness is unquestionably sidebone. It is extremely common amongst draught horses, and its hereditary character has been clearly demonstrated.

Now, what constitutes a sidebone? To clearly understand the term it is necessary for the farmer to know that at the heels of a horse's coronet are to be found what are called the lateral cartilages. These are flexible plates, and when examined in their normal or healthy state they are springy, elastic, and easily moved. They are of much consequence to a horse, and especially

a draught horse, as they prevent undue concussion on the other soft structures inside the hoof. Simple sidebone may be defined as a conversion of the lateral cartilage of the foot into a bony condition by the deposit of lime salts. The ossification of the cartilage may or may not be complete, but if the sidebone is forming, there is the hereditary tendency or taint, and practically to the same extent as if the cartilages had undergone complete bony change.

In order to distinguish sidebones the farmer should accustom himself to the normal condition of the lateral cartilages. Regular examinations of the cartilages, which, when pressed, should be yielding and elastic, ought to be made. Any deposit of bone can be immediately recognised, as the cartilages become quite hard, and often much enlarged.

Amongst a certain section other influences, apart from hereditary tendency, have been attributed as causes of sidebone. These may be enumerated in order as follows :—1. Concussion. 2. High-heeled shoes. 3. Injury to the coronet.

That concussion plays an important part in the ossification of the cartilage cannot be questioned, and it is generally accepted that sidebones develop quickly when horses congenitally predisposed to the disease are worked on hard roads ; but it is extremely interesting to observe the existence of sidebone in young horses (and often a number with family history) which have never worked on hard roads, but have been on soft country since foaled.

To follow up the concussion view. Owing to the nature of their work, it would naturally be expected that light horses, such as hackneys and ponies, would be prone to sidebone ; but during the examinations in this State very few cases were discovered in light horses, and amongst these hereditary tendency was evident.

The fact that none of the horses with sidebone examined in this State were shod with what is termed a high calkin or heel, and a large number had never been shod in their lives, dispenses with high heels as a cause, or even a contributing cause, of sidebone.

Injuries to the coronet in the region of the lateral cartilages occur frequently to draught horses working in teams, and the subsequent appearance of sidebone is sometimes an accomplished fact ; but many horses are injured severely in that region and no trace of ossification of the cartilage can be found. Sidebones which have appeared after injury would have developed without, as the hereditary tendency must have existed.

It is quite a simple matter to test the injury or tread theory, and it will be found that, notwithstanding severe injuries to the coronets, only horses with the sidebone taint will be found with sidebones.

Sidebones are usually found in the fore feet. Sometimes only one cartilage is affected, but as a rule both cartilages in the fore feet are ossified. Occasionally sidebone presents itself in a hind foot, but this is a rare condition.

In examining horses with sidebones it will be observed that a certain class of foot is indicative of hereditary predisposition, viz., those with flat, straight heels. In purchasing horses, horsebreeders would be well advised to pay particular attention, not only to the top of the horse, but also to his legs and feet, and look for animals with strong, well-developed feet, and the heels of which are strong and nicely turned.

It is impossible to state definitely how long it will take for a sidebone to develop. Sidebones have been observed in horses under two years, and are usually well developed before a draught horse is five years of age. Cases are on record in which the lateral cartilages were normal at five years and sidebones appeared afterwards, but such cases are not common.

The lameness of sidebone is characteristic. The stilty action and want of spring clearly demonstrates the nature of the complaint; and on hard roads especially it will be seen that the sideboned horse puts his toe to the ground first.

Treatment for sidebones is practically useless. Notwithstanding arguments to the contrary, sidebone is an hereditary unsoundness of great economical importance to this State, and horseowners who have dearly bought their knowledge and know some of the tainted families should do all in their power to prevent the use of sideboned sires and dams for breeding purposes.

(To be continued.)

AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

CONFERENCE AT COWELL.

A Conference of Agricultural Bureau Branches of the Franklin Harbor District was held at Cowell on Friday, August 2nd.

The following delegates were present :—Messrs. J. W., E., and J. P. Story, H. R., F., and J. S. Jacobs, A. M. and P. G. Wilson, and W. E. Hier (Miltalie Branch) ; G. W. Story, A., J. Y., and J. F. Robertson, N. P., J. N., and A. P. McCallum, F. Beinks, M. Frost, B. Howell (Yabmana Branch) ; A. Ramsey, M. S. Hunt, W. H. Stephens, H. and J. R. Hill, P. H. Sinclair, M. Abrook, T. C. and H. T. Hornhardt, G. C. Bilney, W. H. Gale, D. Holmes (Utera Plains Branch) ; R. B. Deer, S. H. Pearce (Yadnarie Branch) ; G., P. C., A. C., and S. Wake, W. T. Cooper, P. G., H. W., and H. J. Wheeler, A. O. Chilman, A. E. Storey, C. T. Jacobs, F. Freith, G. F. and E. E. Elleway, H. Schumann. There were also present Messrs. W. Lowrie, M.A., B.Sc. (Director of Agriculture), F. E. Place, B.Vc., M.R.C.V.S., G. G. Nicholls (Secretary Advisory Board of Agriculture), and a large number of farmers and others.

A PLEASING TRIBUTE.

Mr. A. M. Wilson, who was voted to the chair, presided over an attendance of about 60. He said that great interest was taken in the work of the Bureau on Eyre's Peninsula. There was room for more Branches at such places as Mangalo, Warren, and Cleve. It was a noteworthy fact that the best farming was in evidence in those places where there was a Branch of this association. There had been considerable activity in the Bureau recently, and new Branches had been formed at the rate of two a month during the past year. He welcomed the delegates and visitors, and expressed great pleasure at the presence of Professor Lowrie in this new district.

THE ERECTION OF FARM FENCES.

Mr. P. H. Sinclair, of the Utera Plains Branch, introduced the first matter for consideration in an excellent paper on "Farm Fencing." "Durability and neatness," he said, "were features which should receive special care in permanent improvements such as fencing. Bad fences caused bad neighbors and much inconvenience generally. The vermin-proof fence was the one needed in this district. A line should be cut and cleared at least 10ft. from any scrub or undergrowth, and the fencing would thus be safe from

bush fires or sand drift. The posts should be of the best material obtainable. If sandalwood or pine could be procured the posts should be cut 5ft. 4in. long and be trimmed free from spurs and splinters. The tops should be neatly cut. He would dig the postholes square all the way down, and 20in. deep. It was best to sink a whole line at a time, and then with one man putting in the loose posts and shovelling in the earth, the work would proceed at a good pace. A post should never be sighted from the back line, and with a light bar for a rammer the plumbing and sighting could be done at the same time without looking at the back line. The boring should be done with $\frac{5}{8}$ in. augers, to prevent the wire from rusting in the holes. The gauge of fence should be as follows :—Posts, 3ft. 6in. high, not more than 12ft. apart, and 36 in a strain ; strainers, 3in. higher than the posts. All strainers in the line should be strutted one way, and the corner post should be strutted both ways. A good strong barb should be put on top with two plain No. 8 galvanized wires and netting below. The first plain wire should be 12in. from the barb, and come flush with the top of the netting, and the second one 11in. from the top of the netting. The barb should be tied on every post with No. 18 wire, and the netting should be tied with small wire three times on to the first plain wire and twice on the second one in every panel. One and a quarter inch mesh netting was most effective against vermin. The trench should be loosened up with a grubaxe and then cleaned out with a round-mouthed shovel, making a clean, wide furrow 5in. deep. This made an excellent sheep-proof fence with the netting on, and if the netting had to be removed when extending the area of cultivation and sheep were not kept, there would still be a good durable three-wired fence proof against large stock."

DISCUSSION.

Mr. A. Venning said he preferred to have the second wire barbed also on the top of the netting, to keep stock from rubbing themselves against it. Mr. Ramsey thought 3ft. 6in. too low for a fence where the land was liable to drift : 4ft. was a better height. In replying, Mr. Sinclair said that a 4ft. fence would have such a gap between the top wire and the netting that stock would put their heads through and soon learn to be troublesome fencers.

SHEEP FOR FRANKLIN HARBOR DISTRICT.

Two practical papers under this title were contributed.

Mr. M. R. Frost (Yahmana) said as the district became settled and weeds spread over the land it became necessary to keep sheep. By the exercise of a little care the sheep could be turned into a very satisfactory investment. The farmer should study his own conditions and work accordingly. For that district the pure Merino was the best breed. Heavy freight and charges prevented the sheepowner from exporting lambs and mutton at a profit, and the local demand for meat was not great, so that wool was the first con-

sideration. By judicious selection of rams the flock could be brought to a high standard. In the choice of a ram, density of fleece should be looked for rather than length of staple. If the ewes were at all fine woolled, the progeny would then carry a heavy fleece of very fine wool. That would weigh well and would command the highest price. At least once a year the flock should be rigorously culled, and the aged sheep and any showing signs of rough or coarse wool passed out. These should be marked off for killing. The sheep which produced the heaviest fleece of good wool would, in nearly every case, prove to be the most profitable.

Mr. C. Mowat's paper read much as follows :—" There is not the slightest doubt that sheep are a paying side line for a farmer who mainly depends on wheat for his income. The cost of keeping, say, 200 sheep, is practically nothing, and one can expect a nice return from a flock of even this small size. It behoves the farmer to buy sheep of good pure strain. The expense may be a little more, but this is a duty to the country, as it will, in years to come, raise the standard of Australian wool. The pure big-framed Merino is hard to beat anywhere, and especially so in this district. Although this class of sheep is admittedly not the equal of Down or Dorset Horn-Merino crossbreds for fat lamb raising, there is no handy market for fat lambs ; therefore, the wool-producing feature is rendered more prominent, and in this the Merino takes one's fancy. As a rule, Merinos will cut a heavier fleece than the crossbred, and, in addition, the market prices for their wool do not fluctuate as for crossbred wool. Merinos also do better in dry country. They are quiet and do not trouble fences when a wheat crop is on the other side, as the crossbreds are so wont to do. Some little labor is required to put up yards, but where there is such a small flock and dipping is unnecessary, this takes only a day or two. In this district it is wise to have the yard dog-proof, as wild dogs are far too prevalent, and tame dogs have developed a taste for sheep. It is advisable to yard the sheep every night, otherwise one's profits may literally ' go to the dogs.' For such a few sheep no special shearing-shed is required, so the expenses of installing a flock are very slight indeed. To get the best results from the pasture available, paddocks need to be fairly small, say, 60 acres or 80 acres in extent. This means extra fencing, but the value of the property is greatly enhanced thereby. The sheep should be turned into one paddock until they have eaten it well off and then turned into another. This is much more economical than letting them run in 200-acre or 300-acre blocks, as by spelling the paddocks the feed has a chance to recover and other stock can be put on it first. In addition, one knows better where to find the sheep when yarding-time comes each night. A flock is very useful in keeping down the weeds on fallow, and in breaking up clods, and making a good seed bed. Some farmers believe in feeding off growing crops to make the plants stool better, but I think this weakens the crop and gives the weeds a better chance. Sheep do remarkably

well on dry feed if they have a sufficiency of water, and this should be assured. It is preferable to have the water in troughs, as all stock pollute the water when allowed access to a dam. A windmill or pump would be required with the troughs. The windmill and floating ball taps are to be preferred, as they keep the troughs full. A lick of rock salt is a good help to keep sheep in condition when feed is dry, and in winter it makes them thirsty and consequently they drink better. A good tonic is sulphate of iron, which can be given to the stock by dissolving it in the troughs. It is essential to have at least two rams per 100 ewes to get the best results. The rams should not be kept too long with the ewes, or lambs will be coming on when feed is going off. The most suitable time to have the lambs coming on is in May, as they catch the feed in its young stage and have a chance to get a bit used to life before the cold and wet weather really sets in. A rough estimate of the returns one could expect from a flock of the size mentioned is as follows:—Wool cut, about 9lbs. or 10lbs. each, would bring £60 clear; and 100 lambs should sell at 7s. each, making £35. A total of approximately £100 per annum, and from such a small expenditure in time and labor, is a handsome return. There is also to be considered the saving in the provision of mutton for the house. It is hard to put a definite value on the work done by the sheep in cleaning and manuring the fallow, but as work saved means money gained, that must be put to the credit of the sheep. A farmer who is not keeping sheep is not getting as good a return from his land as he should."

THE DISCUSSION.

Mr. Jacobs and Mr. Storey (Miltalie) had both kept sheep for many years, and were convinced that they were a paying proposition when worked in conjunction with wheat-growing. Mr. Jacobs had tried the Shropshire cross, but they were such bad fencers that he cleared them out. All things considered, the Merinos paid best. Mr. Storey preferred not to yard the sheep, as this practice reduced the value of the wool.

Mr. T. W. Storey (Yabmana) thought it best to breed for length rather than density of staple. Both these qualities could be secured in the Merino.

In replying, Mr. Frost said there was a tendency on farms to get the wool long and coarse, and he therefore advocated the use of rams with density and quality of staple.

AGRICULTURE AS A PROFESSION.

The Chairman (Mr. A. M. Wilson) read an interesting paper, in which he said that the day had gone by when "any fool" could be a successful farmer. Not only did the farmer need brains, but educated brains. Science had come to the aid of the agriculturist by investigation, collection, and recording data relative to crop-raising and stock-breeding, &c. Many farming practices which had long held sway had, by careful test, been found unreliable, and

others had been suggested which had led to greater returns being won from the land. Observation and the power to make logical deductions were important qualifications to the farmer, but further knowledge was also necessary. Chemistry, as applied to the soil and to stock complaints, was a study worthy of attention by farmers, while some knowledge of physiology, geology, and botany was of great value. The farmer had to ascertain the nature and needs of the different soils on his holding, both in regard to fertilisers, depth to cultivate, and general treatment, as well as the crops or varieties of seed most suited to it. He must study the laws of breeding, and know something of the relative value of various foods if he would win the highest return from his labors. Much could be learned by careful experiment to supplement that knowledge gained from the study of the various branches of science enumerated. Considerable knowledge of mechanics was necessary, that the maximum of power might be secured at a minimum expenditure of energy. A knowledge of blacksmithing, masonry, and carpentry was essential on the farm, where buildings had to be erected, tanks constructed, implements repaired, and engines and machines kept in order. The farmer also had to keep in touch with market reports if he would sell to the best advantage the produce of his land. He should have a "den" or study, and procure the latest books relative to the various phases of his calling, and should encourage his sons to develop the same habit of reading to keep abreast of the times. In conclusion, the writer appealed to the patriotism of the farmer to make the best use of his land in the interests of his country as well as himself.

THE DISCUSSION.

Mr. J. N. McCallum (Yabmana) thought that bone and muscle, coupled with some enthusiasm, were the main essentials to successful farming. The power of observation should be developed to the highest possible degree, as this enabled the farmer to correct his practice from time to time by the results of his own and his neighbor's experience and results.

Mr. G. G. Nicholls urged the wisdom of carefully studying the various articles and papers printed in the *Journal of Agriculture*, and advised all farmers to procure the Victorian and New South Wales *Journals* in addition, as these contained most valuable contributions which were, in many instances, applicable to conditions in South Australia.

DESTRUCTION OF WEEDS BY FALLOWING.

A discussion on this subject was initiated by Mr. G. B. Kobelt (Yadnarie), who advised farmers to keep their land as free from weeds as possible. Weeds became a great enemy to the wheatgrower. Already he had noticed in that district four fast-spreading weeds—Scotch thistle, turnip weed, dandelion, and stinkwort. The last-named, it was claimed, loosened and enriched the soil. He had never found it any good, as it robbed the fallow of moisture,

and a thick growth would choke any cultivating implement. Farmers who had the necessary strength should not be afraid to put a little extra draught on the plough to pull up as many green stumps as possible, because mallee country, logged and burnt, was really only half cleared. Land from three to four years old should be ploughed up to a depth of 5 in. New land should be ploughed not deeper than from 3½ in. to 4 in. He believed it was better to fallow newly-burned land than to leave it lying idle until the following seeding time, as otherwise the rain would not easily penetrate its ashy surface. In addition, that course facilitated seeding operations in a dry autumn. Weedy fallows should be worked at least twice before the drill was used. He advocated working with a light cultivating plough just before hay time, to prevent all weeds from seeding. The second working should be done a few days after the first summer rain. This would stop the growth of young weeds. The farmer who attended to the destruction of weeds at the proper time got the best results.

THE DISCUSSION.

Mr. McCallum considered fallowing should be finished by August. Mr. W. Cooper thought wild turnip was the worst weed in the Elbow Hill district, while dandelion and stinkwort came next. No rule could be laid down as to the depth to fallow, as this depended on the character of the soil. He would finish his fallowing before August, if possible, and harrow after every good rain. The Chairman thought it advisable in some circumstances to fallow land two years in succession, in order to get rid of the weeds.

FIELD TRIALS.

The matter of making field trials of implements more successful and of greater value was introduced by Mr. C. E. Jacobs, of Elbow Hill. He thought that field trials should be encouraged rather than agricultural shows in new districts where smart turnouts were a luxury. Field trials gave settlers an opportunity to exhibit a good team, and brought implements into the district for open trial before the farmers.

Mr. Robertson (Yahmana) thought there was room both for the field trial and for the show, but the country selected for the trial should be of such a nature as to provide a genuine test. Such trials had been held on well-cleared land. Other speakers urged that the field trial was of great value to the farmer.

AFTERNOON SESSION.

About 80 farmers assembled after lunch, when questions concerning stock were answered by Mr. F. E. Place, B.V.Sc., M.R.C.V.S., at the close of a veterinary demonstration.

LOCKJAW.

The tetanus germs, Mr. Place said, were present in certain places, particularly in dirty stables, and entered the animal through wounds such as

might be made by a stake, barbed wire, or wounds in the bowels made by worms. The symptoms of the disease were then described at length. Given reasonable conditions, the speaker said, nature would fight against the trouble. If the weather was good he would leave the patient alone. If cold and wet prevailed, he should be placed in a dry stable and well looked after, having sloppy bran mash in which some Epsom salts should be administered. The salts could also be given in the drinking water, but drenching should not be resorted to. The animal should be kept as quiet and as comfortable as possible.

EFFECT OF WORM POWDERS ON MARES IN FOAL.

Tartar emetic and santonin, the speaker said, were both liable to upset a mare sufficiently to cause her to slip her foal. Both these drugs would upset a mare's digestion if given in sufficient quantity, and so would be likely to upset the unweaned foal. It was best to keep off all these drugs under such conditions.

BOTS.

Mr. Place explained that the bot fly laid her eggs on the hair of the horse in several parts, where they remained, adhering by a sticky substance with which they were coated. Within about 36 hours they hatched, and the tiny maggots, if such term might be used, caused intense irritation to the horse by wriggling. The animal, in trying to rub them off, got them into its stomach, either directly through the mouth, or by rubbing them into the manger and picking them up in the food. They then became firmly attached to the lining of the stomach by two horny spikes. The bots were capable of throwing off oil, water, acid, or salty substances, and if these were administered the bots would hang tight and continue to suck the blood of the horse. If a man suspected that his horse was troubled with bots, he should starve it for 24 hours, and then the first thing in the morning give 4ozs. or 5ozs. of ox or sheep gall in a pint of lukewarm milk; and then, two hours after, give a purgative of raw linseed oil. Bots were not often responsible for the death of horses, but they lowered the condition of the animal and some other complaint killed them.

IMPROVEMENT OF BUREAU MEETINGS.

A practical paper on this subject was delivered by Mr. Jacobs, of the Miltalie Branch. Mr. Jacobs urged that members as a first duty should be regular and punctual in attendance, and should be prepared to take an active part in the discussions which occurred. They should also take a turn in reading a paper or opening discussion on seasonable and important topics. There was no reason why members should be bashful, or afraid that their efforts would be discounted by grammatical or other errors. What was needed was a plain statement of experiences or opinions. Some men left their paper-writing till the last moment, and were then unable to give their subject

that consideration that it deserved. Homestead meetings were of much value, and should be arranged periodically.

Mr. Searle spoke of the benefit which he had personally derived from his association with the Bureau. There was much to learn, and science was bearing more and more upon the cultivation of the soil. The Bureau members should constantly aim to keep in touch with what the chemists and biologists were doing, and relate the knowledge gained to their calling upon the land.

Mr. G. G. Nicholls urged upon members the advisableness of conducting experiments upon their several farms, that they might have more valuable data to discuss at their meetings. The amount of super. which would give the greatest profit per acre, for instance, could only be proved by careful experiment. It was time for the Bureau to take up more work of this kind. The papers which were of greatest value to Branches and of most interest to readers in the *Journal* were not always those which were expressed in flowery language or were faultless in grammar. Any little touching up necessary was seen to before printing. Members' own experience, and the conclusions at which they had arrived by observation and deduction, were usually well worth consideration by others.

RABBIT DESTRUCTION.

This question was introduced by Mr. G. F. Wake (Elbow Hill). Rabbits were a pest, he said, to both graziers and farmers. The authorities who were responsible for the administration of the laws relative to the destruction of rabbits were not strict enough at the right time of the year. He considered all landholders should be compelled to lay poison at a fixed time, just after harvest. He followed this method, and then strewed baits of phosphorised pollard in each burrow. After a few days he filled in the burrows with a grubber. Later in the year he dug out the opened burrows and set a few traps. The dogs then got the stray rabbits, and in this way the whole lot could be cleared out. He would be prepared to give 1s. per scalp for any rabbits which could be found in one of his paddocks treated in this manner. The fences must, of course, be kept in good repair. He used 3ft. netting, trenched 4in. to 6in., and fastened to a wire in the fence. Mr. J. J. Deer thought the existing laws were quite strict enough. The best way to get rid of the rabbits was to poison in summer, fumigate in winter, and explode the burrows. Mr. P. H. Sinclair thought it best to dig out the burrows. It was labor well spent. Mr. Searle considered the Vermin Boards had too much to do, and that there should be a small board of, say, three men to enforce destruction.

NEXT CONFERENCE.

It was decided that a committee should be appointed, representative of the Branches of the Bureau in the Franklin Harbor District, next year to make all arrangements for the next Conference.

EVENING SESSION.

There was an attendance of about 150 at the evening session, which was opened with a free parliament. The Director of Agriculture (Professor Lowrie) delivered an address dealing with the cultivation of the soil for wheat-growing.

EXHIBITS.

Samples of the produce of the district were staged in the hall, and comprised capital specimens of cabbages, turnips, swedes, Chinese radish, silver beet, wheat in ear, barley 3ft. high, and chaff.

Votes of thanks to the Chairman and speakers brought the proceedings to a close.

CONFERENCE OF BRANCHES IN PINNAROO DISTRICT.

The first Conference of Branches of the Agricultural Bureau situated in the Pinnaroo district took place in the Institute, Lameroo, on Friday and Saturday, August 23rd and 24th. In addition to the Minister of Agriculture (Hon. T. Pascoe, M.L.C.), the Director of Agriculture (W. Lowrie, M.A., B.Sc.), the Veterinary Surgeon (Mr. F. E. Place, M.R.C.V.S., B.V.Sc.), Messrs. A. M. Dawkins (Chairman), F. Coleman (Advisory Board), and H. J. Finnis (Department of Agriculture), the following Branches were represented by the delegates named below:—Pinnaroo—Messrs. P. J. Edwards, E. H. Parsons, B. H. Nash, P. H. Jones, J. Scales, F. H. Edwards, A. J. Reed, W. H. Kelly, J. Letheby. Parrakie—R. L. Beddome, C. E. Hammond. F. J. Dayman, T. Lewis. Geranium—W. Mitchell, P. Jacob, D. Leahy. W. Pannell, W. J. Mitchell, G. Charlton, C. Reed, F. Norton, C. D. Dunn. Moorlands—C. F. Bauer, R. Neumann, A. Oppat, L. Spurr. Wilkawatt—D. F. Bowman, W. J. Tylor, M. Neville, J. Walters, F. Gasmuir. Lameroo—Crosby, W. J. Trowbridge, A. J. Koch, F. W. Eime, R. O'Connor, R. B. Koch. Parilla Well—J. Gray, J. W. Johnston, E. H. Leak, J. E. Johnson, R. M. Shannon, L. G. Neville. Clanfield—W. Paul, A. Richards, W. Queale, A. Orwill. A large number of visitors also attended each session.

The chair was occupied by Mr. W. J. Trowbridge, President of the Lameroo Branch.

MINISTER'S OPENING ADDRESS.

In opening the Conference, the Minister said he was agreeably surprised at the wonderful transformation which had been effected in the district since his previous initial visit in 1902. Judging by what he had seen and read the settlers had done great work, and the district had become one of the foremost wheat-producing areas in the State. He was glad that the farmers were banding together for the purposes of mutual education and help. The officers of the Agricultural Departments in the other States placed the South Australian tillers of the soil in the forefront, and had attributed their progressiveness mainly to the influence of the Agricultural Bureau. The Victorian Director of Agriculture recently said he had been astounded to find the South Australian farmers in Conferences holding their own with professors and agricultural experts, and had admitted that such a thing was utterly unknown in his own State. He had added that it was simply glorious to attend a Conference at which South Australian agriculturists were present, because of the intelligent interest which they manifested. One evidence of the intelligence of the farmers in that district was that they had formed a Branch of the Bureau. That innovation had been made at Lameroo only five years ago. To-day, between Tailem Bend and Pinnaroo, and including Clanfield, there were nine Branches. It was gratifying to reflect that the Bureau system was extending rapidly all over the State. During the last 12 months Branches had been formed at the rate practically of one a fortnight. Now the organizations totalled nearly 140. Not only had the number of Branches increased, however, but the Upper Northern District Conference had been revived, and new district meetings had been inaugurated on Yorke's Peninsula, on Eyre's Peninsula, and in the Pinnaroo district. When they realised what the Bureau system had done for farmers they looked forward with the greatest hope and confidence to the future. Personally he believed that the men on the land in South Australia had only just learned the first principles of agricultural science, and what they had done was as nothing compared with what they would accomplish. He had noticed with pleasure that at a recent meeting of the Lameroo Branch the members had unanimously expressed the opinion that excellent benefits would be derived in that district from fallowing, and he felt certain that, generally speaking, when once they had properly cleared their land of shoots and stumps it would pay them to put in 50 per cent. less in the way of crops, because they would probably get 50 per cent. more from the reduced area by means of thorough and scientific cultivation. It was a keen satisfaction to him to attend the Conference, and he sincerely trusted, in declaring it open, that it would prove to be of the utmost benefit to all.

REMARKS BY THE CHAIRMAN.

Mr. Trowbridge said he greatly appreciated the honor of presiding over the first Conference of the Bureau held in the Pinnaroo district. He accorded

a hearty welcome to the visitors, and trusted a profitable time would be spent by all. The value of the Bureau system could not be overestimated, and he suggested that other Branches should annually hold a "Report meeting." Some time ago the Lameroo organization had set aside one day when each member furnished a comprehensive report covering his tillage and seeding operations and the yields obtained. The innovation had delighted everybody and had been most instructive. Other Branches probably would have equally encouraging results.

AFTERNOON SESSION.

SAND IN HORSES.

The Veterinary Lecturer of the Department of Agriculture (Mr. F. E. Place, M.R.C.V.S., B.V.Sc.) delivered an interesting address on this subject. There was a tendency amongst stockowners, he said, to ignore what appeared to be trifling illnesses, until the condition of their animals forced home to them that there was something radically wrong. Sand was the cause of a great deal of trouble in districts like those of the Pinnaroo hundreds. The symptoms arising from the introduction of sand into the stomach and bowels of the horse included loss of condition, falling in of the flanks, sagging of the belly with a bulging on the right-hand side, paleness of the eyes, casual griping pains, and voiding with the dung. The action of the sand was to choke the glands in the stomach and bowels, to choke the glands of the pancreas, interfering with the flow of bile from the pancreas, and cause the silting up of the blind gut, better known as the paunch, which ordinarily should have from 7galls. to 7½galls. of very liquid contents, which had to leave by an opening higher up than that by which it entered. The clogging action of the sand, which induced the glands to greater activity to remove the obstruction, was often followed by a weakness of the organs, and the settling of a sediment of sand on the lining of the various membranes.

The time to be concerned about a horse was when it was turned out on sandy pastures, as it was certain to get sand into its system. Over the border, many people recommended the administration of strong coffee, and its value was due to its stimulation of the nervous action which enabled the organs to break the settled sand and assist in its ejection. It was a wise plan now and again to give the horses a good dose of coffee (½lb.) mixed with their feed, or to administer as a drench. Other home remedies included honey and milk, and both were scientifically sound. The honey had a stimulating effect upon the working of the small bowel, and hastened the sand through in a loosened condition to the larger bowel, whence it was passed out more easily. New milk coagulated in the stomach and gave off gas which broke up the cementy condition of sand in the intestines, thus giving the bowels a chance to expel the matter. He did not think they could get drugs to give better results, as their action was directed to the same task

as the homely remedies mentioned. As preventive treatment he advised careful observation of the horse's physical condition, and when the first symptoms were noticed, giving the animal something in his food to hasten the action of the bowels. He emphasized the value of bran mash and boiled wheat. Pollard also was good, but by the time it was in a condition to treat the sand it had lost a good deal of its power. If horses slightly affected with sand were fed with boiled wheat the trouble would generally be removed. Its value depended on its action in loosening the sand.

LAMPAS.

Mr. Place condemned the practice of burning out "lampas," which was an imaginary disease. Such treatment destroyed the animal's mouth pads, which were probably temporarily inflamed by the process of teething. In some cases, where the inflammation was aggravated, bleeding was practised. Farmers could safely use the kitchen fork for the operation, as stabbing with the knife was liable to tap the arteries which were situated in the mouth above the teeth.

THE BOTFLY.

The life history of the botfly was traced by the lecturer, who advised the treatment of infested animals with sheep or ox gall. In reply to questions, Mr. Place said from 7lbs. to 8lb. of boiled wheat a day was sufficient for the horse. Molasses was useful in helping the animals to get the full nourishment from their fodder, but was not sufficient remedy for sand. Epsom salts, at the rate of 4ozs. once a week, was a useful laxative, and to that extent was a preventive. As a purge he preferred aloes balls to salts.

EVENING SESSION.

WHEAT-GROWING.

The Director of Agriculture (Wm. Lowrie, M.A., B.Sc.) addressed the Conference on the subject of the cultivation of wheat in the Pinnaroo district. A modification of established practices, he said, would no doubt be found necessary by the farmer taking up the mallee land. If a criticism could be offered in respect to the general tendency, it was that in the first few years settlers were in too great a hurry to clear the whole of their land. It would be better to concentrate their energies more on a part of their blocks, and to leave the remainder of the scrub untouched until it became possible to deal with it effectually. If, at the outset, they put the fire through the major portion of their properties without having made provision to properly cope with the area so treated, a big percentage of the shoots which subsequently came on would get too far ahead, and the clearing ultimately would prove to be a more difficult and costly matter than if the scrub were completely disposed of a little at a time. Not only would the neglected roots gain renewed

vigor, but they would also contend with the wheat plants and draw moisture from a greater depth. In other words, by endeavoring to get over too much land they would get a lower return from a definite area than would otherwise be the case. A feature of the mallee country was the sudden variations in the soil. Within a few miles they had very free, soft, sandy soil, and fairly strong, good wheat-growing land. The systems and periods of cultivation should therefore vary considerably. As a matter of fact, however, the tendency was toward a common practice throughout the district. Still, he was convinced that experience would demonstrate conclusively the desirableness of adopting different methods according especially to the physical constitution of the soil. The principal process to which their thoughts turned was that of fallowing—the keynote to successful farming over the greater part of the State. To illustrate the effects of fallowing at different periods he had had some soil analyses made at Parafield Experiment Farm and at Roseworthy. The figures obtained amply indicated the advantages of fallowing, and of doing the work at the proper time. It had been found at Parafield, on February 22nd, 1912, that in the first 6in. there was an average of 2·7 per cent. more moisture in fallow than in grass land; in 12in. the average percentage was 18·76 in the fallow against 11·45 in grass land; and in 24in. the percentages were 19·37 and 14·25 respectively. That difference of nearly 7 per cent. in the fallow at 12in. meant approximately 32,000galls. of water to the acre, which was equal to 1½in. of rain. It might be accepted as a fact that by fallowing they could ensure an advantage of moisture equivalent to between 3in. and 4in. of rain in the soil within the area which the roots of the plants could readily reach in the course of their growth. At Roseworthy tests of the soil had been made at various depths when the land was ploughed on August 24th, 1911, September 9th, and February 21st. The results were as follow:—August, first 6in., 4·6 per cent. of moisture; 6in. to 12in., 13·3; 12in. to 18in., 17·3. September, 4·2, 13·6, and 15·3 respectively. February, 2·2, 8·2, and 13·9 respectively. They would see that there was a distinct difference in favor of early fallowing, and an advantage which might be worth to the owner quite as much as the fallowing cost. Heavier types of land were benefited to a greater degree than the lighter classes. The rain penetrated fairly freely into most of the sandy soils, but was more difficult to get into the heavier land. The latter, it was true, held more moisture than the former, but when once well saturated they gave the moisture off more rapidly and dried more quickly because the capillarity was more active. Fallowing and the working of fallows, therefore, became the more important where the land was compact and heavy. Ploughing early in the season was in favor of getting the rain into the soil. Having by this means secured the moisture, evaporation could be reduced to a minimum by providing a good surface mulch. The lighter lands should not be worked dry. He believed it had been agreed that in these the roots of the

plants penetrated much more freely, and reached a greater depth without anything like the same encouragement in the early stages in the way of opening up the land than obtained in respect to the heavier classes of soil. He could easily conceive that there might be some light, sandy soils in the new districts which would be benefited considerably by ploughing fairly deeply, thus mixing up with the surface soil at least a proportion of the lime which had been leached down. There was a likelihood that some of the young farmers particularly worked their fallows excessively. So long as they had a free surface it would be well not to go on the land too much. Instead of helping to retain the moisture, excessive working helped to dissipate it through turning up moist soil. It would be sufficient after a rain to put the harrows over the land. A most important feature of cultivation was the inducement of nitrification—the breaking up of the organic matter through the agency of the numerous ferments. These required air and moisture, and thrived best when the temperature was 90° or over. Consequently it was essential to get as much moisture as possible into the ground at the earliest moment. Ploughing late in the season and opening up the land to the bottom of the furrows brought about conditions too dry for healthy ferment life. Early fallowing led to the increase of ferment activity, which was much more important than the gain of 3in. or 4in. of rain. He could not understand why many men this year had put in crops in June and July. They would have been better employed fallowing the land for the next season. On the whole early seeding undoubtedly worked out the best. He had had 17 years' experience in South Australia, and that was the worst season he had ever witnessed. Where there was danger of spring frosts it was advisable to use later varieties of wheat.

MORE MANURE.

He strongly advocated the application of heavier dressings of phosphatic manure. It was regrettable that the light dressings of from 40lbs. to 60lbs. had become so popular, because with each crop they took off they removed more phosphoric acid (in which the South Australian soils were deficient) than they put on. Dressings of 100lbs. of superphosphate, and even more, would be amply repaid, for the fertility of the soil would then be maintained, and perhaps enhanced. The additional manure would also facilitate the growth of natural herbage, and thus indirectly increase the humus in the soil—a most desirable element in connection with the retention of moisture. One of the best of these plants was the clover burr—an excellent forage, and of manurial value in that, being a legume, it introduced nitrogen to the soil. To hasten the establishment of a sward it would be well to go into some of the old farming districts, gather up quantities of clover and other seeds, and distribute them upon the land, especially on the lighter soils.

QUESTIONS.

In answer to questions, Professor Lowrie advised that where takeall had affected the wheat, the stubble should be burned in preference to being ploughed in. Otherwise spores of the fungus which caused the disease would be merely buried in the soil. Oats were not a host for the takeall fungus, and therefore made a good crop on affected land. In fallowing after takeall, care should be taken not to allow speargrass to grow, because it would carry the disease over to the next wheat season. Rolling wheat crops increased the evaporation of moisture. He did not advocate rolling on the ordinary wheat lands, although if the crop were required for hay it might be done with advantage, providing harrowing was carried out afterwards. Rolling on the finer sandy lands, while compacting it, would not do so closely enough to make the loss of moisture from the surface very appreciable. When at Roseworthy College he had rolled and harrowed portions of crops, no difference could be noted between the rolled and untreated areas, but the benefits from harrowing had been distinctly traceable. The latter operation could take place even when the crop was 5in. or 6in. high, providing the weather was suitable. He advised, where fallow was concerned, to harrow after light rains, and scarify after heavy falls. Fallow should be left rough early in the season, and harrowed down by the middle of August. Mallee limestone land was never too wet to work. Lime should not be applied to any soils along with superphosphate, as the contact caused a reversion of the latter into an insoluble condition.

PEA CROPS.

Pea crops supplied one of the best means of increasing soil nitrogen and organic matter. In Western Australia, near York, where the average rainfall was from 16in. to 17in., a farmer had depastured sheep on his pea crops, and their increased value had netted him £3 5s. per acre. The American and German Departments of Agriculture had, as a result of careful researches, estimated the gain to the land from growing crops of peas to be 122lbs. of nitrogen to the acre in one case, and in the other 160lbs. Eight hundred weights of nitrate of soda would be required to supply 122lbs. of nitrogen, and the cost would be £6 12s. Nitrogen, of course, was required with the soil throughout, but the wheat made more demand on the supplies when making rapid growth just before blooming. Clovers supplied nitrogen, but could not be grown in that climate with the same success as peas. In reply to Mr. Shannon, who desired to know if there was any danger of lucerne choking out wheat in the district where there was an average rainfall of over 14in., Professor Lowrie said he did not think they would make a success of lucerne. Mr. Shannon and others, however, cited instances of the successful establishment of plots, and the Professor advised those who could grow this fodder to do so.

FREE PARLIAMENT.**NOXIOUS WEEDS.**

The following resolution was proposed by Mr. S. Parsons (Pinnaroo):—
“That the Conference bring under the notice of the district council the great need for the enforcement of the Noxious Weeds Act in the district.”

While, up to the present, residents in the district had not been troubled with the numbers of weeds which were such a nuisance in the older parts, little attempt was being made to prevent the introduction and spread of these, and immediate action in this direction was imperative. Mr. P. H. Jones (Pinnaroo) seconded. Mr. A. M. Dawkins (Advisory Board) described the attempts made by the Board to secure effective administration of the Act. The Government had been asked to take action, but had replied that the request should come through the local governing bodies. They should get the district councils to bring the subject before the annual meeting of the Local Governing Association. Mr. Coleman, in supporting the motion, stated that if farmers allowed the star thistle to become established, it would cause a great deal of trouble and expense. The resolution was carried.

MORNING SESSION.—AUGUST 24th.**HAY-GROWING IN MALLEE DISTRICTS.**

Mr. F. W. Eime (Iameroo Branch) read the following paper:—

“Farmers in new mallee districts should study the hay supply for their horses before anything else. During the present season some had to buy feed for their horses in order to put their seed in. Persons who have been three years in a new district should be able to grow enough hay to last at least 12 months for their working stock. In good seasons a little more hay than is immediately required should be cut to help over a dry period. I recommend a farmer who has from 16 to 20 horses to feed, to fallow about 60 acres early in July. All stumps should be cut level with the ground, and loose stumps and shoots cleared. It should be worked several times until a fine tilth is secured. Before planting the seed, if possible, the land should be cultivated after rain, then drilled first one way with 40lbs. of wheat and 50lbs. super., and then across with the same quantity of manure and wheat or oats. I should put in half the plot with oats crossed with wheat, and the other half with wheat. Should the season be a good one, from 2 tons to 2½ tons per acre should be cut, or in a season like the past one, from 1 ton to 1½ tons per acre. Even if only 1 ton per acre were cut, enough hay to last for the year, and in a good season, to spare, would be grown. I have grown 2½ tons of hay from wheat and oats cross-drilled on a plot of six acres, it being the fifth crop in succession; and during 1905, 1 ton per acre was secured without any manure, 40lbs. of seed being sown. This proves that

the district will grow the required feed if only the land is treated in a proper manner."

Mr. Dawkins (Advisory Board), in congratulating the writer of the paper, said it would pay the farmers in the mallee country to go to some little trouble in preparing 40 acres or 50 acres for the purpose of providing feed for their horses. Oats should form a large part of the crop for hay, as horses did very well when fed on oaten hay cut at the right time. In the Gawler River district this crop had to be cut just about the time the straw began to turn purple. In addition, owing to its immunity from takeall, oats was an excellent seed to sow on land where this fungus was troublesome. The best time to cut wheat was when the grain was in the milky stage, before it became hard, and just after it had flowered. He believed in feeding a fair amount of long hay to the horses. The only way the farmers could ascertain the best wheats for hay for the district was by experimenting. The most suitable wheat, so far as his land at Gawler River was concerned, was Leak's Rustproof. It would suit the Pinnaroo district well, but should be sown early. White Tuscan was another excellent variety. The hay had a beautiful aroma, horses were very fond of it, and it yielded a good cut. Indian Runner was a high-growing wheat which made it difficult to handle. Le Huguenot was a good variety, but it did not stool well; mixed with oats it made a good hay.

Mr. C. F. Bauer (Moorlands) did not think the trouble and time spent in cross drilling were warranted. If oats and wheat were mixed together, and the mixture were sown through the oat device on the drill, equally satisfactory results would be obtained. The finest crop of hay grown in the district was cut from a seeding of equal parts of Yandilla King wheat and oats. White Tuscan was a very nutritious fodder, and it could be grown well in the locality. The trouble with the Le Huguenot was that it was so difficult to bind.

Mr. J. Gray (Parilla Well) was disappointed that the district had not produced enough hay to provide for its own requirements. In addition to growing sufficient for the upkeep of 20 horses, he had, during the past season, been able to dispose of upwards of £200 worth of hay to his neighbors. There was not the slightest reason why the farmers should not produce their full requirements in this regard. He had mixed Marshall's No. 3 with Le Huguenot, and an excellent class of hay had been the result. He cut his crop fairly green last year, and it was the best sample of hay he had seen since he came to the district. His practice was to feed a fair amount of bran and pollard to his horses, and they were doing very well.

Mr. J. W. Johnston (Parilla Well) believed in carrying a two years' supply on the farm. He had found the practice of cross-drilling wheat and oats a great success.

Mr. Crosby (Lameroo) had tried the cross-drilling of wheat and oats on stubble land, but it turned out a failure.

Mr. D. F. Bowman (Wilkawatt) pointed out that if a stack of wheaten and oaten hay mixed were kept for two years a great deal of trouble would be caused by the mice severing the bands of the sheaves.

Mr. F. Norton (Geranium) believed the practice of most farmers was to grow the wheat without considering whether it was to be cut for hay or grain. The better way was to sow those varieties which were best adapted for the purpose when hay was required.

Mr. F. Coleman (Advisory Board) had, during the morning, been driven around part of the district, and he expressed the opinion that if good crops of hay were to be grown it would be necessary to give a somewhat heavier seeding than seemed to be the general rule. Federation was not a hay wheat, but it was decidedly better than Yandilla King. The best of all, perhaps, was White Tuscan; but for an early wheat, King's Early would be found very suitable.

Mr. W. J. Trowbridge (Lameroo) said the experience of the past season had impressed on the farmers the necessity of making ample provision of feed for their horses. The district was undoubtedly capable of yielding sufficient to meet its own requirements; all that was necessary was that the farmers should thoroughly cultivate their land, and use judgment in the selection of the varieties of seed sown.

Mr. F. W. Eime, in replying, said two years ago he had a crop of White Tuscan which was as high as the backs of his horses, and he felt sure this variety was the most suitable for the district. His practice was to sow 1 bush. of seed to the acre.

FARMING IN PINNAROO DISTRICT.

Mr. W. J. Mitchell (Geranium Branch), in an interesting paper, discussed the methods of farming adopted in the Pinnaroo district. The blockholder rolled his mallee, burnt it, put the cultivator or skim plough over it, and then drilled in the seed. The stubble was then burnt and the skim-plough or cultivator again brought into requisition. New mallee land required to be cropped twice to assist in the killing of the shoots, and after the two crops had been taken off, it should be left out for fallow. In all mallee country it was necessary during the first few years to adopt methods of farming that were somewhat loose; when the land was free of shoots and stumps more systematic working would be necessary. Occasionally a farmer was met with who drilled in the seed after a burn, without first working the land. This practice was to be severely deprecated. The skim plough could be used with advantage with the first two crops. This implement would destroy any self-sown wheat or weeds on the land. If harrows and skim-ploughs were used more in this country, and the cultivators used less, better results

would be obtained. In the majority of cases where land was left out for the first fallowing, it was worked with the plough or a disc, and then left until seeding. A disc or other light implement was then put over it. Results of from 12bush. to 20bush. to the acre were secured from land treated in this way during the past season. Wellworked country held the moisture, and there was not a farm in the district which was well worked last year that did not yield a good crop. When it came to fallowing, it was better to work a small area well than to carelessly treat a large stretch of country. There was no reason why every farmer in the district should not grow sufficient hay for his own requirements, vegetables for his household, and keep a flock of sheep on his farm.

THE DISCUSSION.

Mr. M. Neville (Wilkawatt) did not favor the idea of cutting down a large area of scrub the first year. It was better to cut a small area and kill the shoots on it before any more was rolled, otherwise the shoots would get ahead of the landholder and, in addition, where the large area was rolled, a greater strength of horses and more implements were required.

Mr. J. Gray (Parilla Well) considered the area put in should be governed by the capital available. He had put in 900 acres with 11 horses the second year he was in the district. The whole of his block was put under crop the next year. Keeping the shoots under entailed a great amount of work, but now the farm was in fairly good order. When heavy rains were experienced in the summer there would be difficulty in getting a burn to kill the shoots. It would cost more to clear two-year-old shoots than it would to clear the virgin scrub.

Mr. F. J. Dayman (Parrakie) believed in getting the whole area down early. A heavy disc cultivator would cope with the shoots even up to three years old. His plan was to clear as large an area as possible, and fallow any of it that could not be cropped.

Mr. F. Norton (Geranium) thought the shoots were the greatest trouble with which the farmer had to deal. While in the first instance the disc was an excellent implement for use in the district, the mouldboard plough was far superior for fallowing. The rougher they could leave the fallow during the winter the better.

Mr. W. Pannell (Geranium) had about 500 acres fallowed last year. He turned back 120 acres of it a second time, but the portion so treated showed no difference in the crop.

Mr. R. M. Shannon (Parilla Well) had had 200 acres in for five successive years. The first year he cultivated and drilled it, and the return was 7bush. to the acre. The failure was attributed to the bad burn. The second year the stubble was light, and he could not get a fire over it. The disc cultivator was put over the land and the seed drilled in before the rains came, with

the result that he reaped 14bush. to the acre. The third year he burned the stubble and drilled after the rains, and the crop averaged 20bush. The fourth year it was subjected to similar treatment, and 18bush. resulted. Last year, the fifth, a good stubble burn was secured, and the crop, a good portion of which was cut for hay, gave promise of yielding about 14bush. An average annual yield of 14bush. to the acre for five years spoke well for the country. He quite believed that after the first few years it was necessary to adopt a better system of farming in this district than was being carried out in many instances. Deep ploughing, however, would never be necessary in the Pinnaroo district.

M. F. W. Fime (Lameroo) put in his first crop in 1905 with the aid of a three-furrow plough, without manure, and he reaped 11bush. to the acre. His experience was, however, that it paid to farm well.

Mr. F. W. Trowbridge (Lameroo) believed in getting over as large an area as possible. If the landholder did not burn his scrub, it was quite likely that a fire from some other holding would go through it and he would have the burnt sticks to deal with. The disc plough was very useful in assisting in the destruction of shoots, but its place was not on the cleared farm. Stumps were a great source of trouble, but it was better to have them out of the land than in it. His experience was that where a good stubble burn was obtained there would be little trouble with the shoots. He did not believe in leaving out a large area for feed for stock, preferring to put in rye, or some similar crop, for the purpose.

Mr. W. J. Mitchell (Geranium) in replying, recommended the cutting of shoots in January or February, when the sap was up. They were then more likely to be destroyed.

NEXT CONFERENCE.

It was decided that the next Conference should be held at Pinnaroo, the arrangements being in the hands of the local Branch.

ADVISORY BOARD OF AGRICULTURE.

Dates of Meetings—

September 4th, October 9th.

THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the department for fuller particulars concerning the work of this institution.

REPORTS OF BUREAU MEETINGS.

Edited by GEORGE G. NICHOLLS, Secretary Advisory Board of Agriculture.

UPPER-NORTH DISTRICT.

(PETERSBURG AND NORTHWARD)

Carrieton, August 22.

(Average annual rainfall, 11½ in.)

PRESENT.—MESSRS. E. W. Radford (chair), M. Manning, F. Williams, F. Vater, J. F. Fisher, W. Boerworth, T. Fuller, J. Ormiston, and J. W. Bock (Hon. Sec.).

FARMING OUTSIDE GOYDER'S LINE.—The Hon. Secretary read the following paper on this subject:—"I have been living and farming in this district for over 32 years, and have found that the conditions obtaining are very different from those in country where they have a much higher rainfall. If the rain falls at the right time of the year in this district, wheat will give a fair return. The greatest trouble is that very often a dry spell sets in about September, and if the rain has been light during the winter months the wheat plant suffers for want of moisture. Science teaches us that we can, to a very great extent, improve matters by cultivation; that is to say, by early fallowing and working the land after every rain. I am very sorry to say that so far very little has been done in this line in the district. As a rule, the fallowing is done too late; the ground is simply ploughed and left as it is turned until next seeding, and then very often put in as quickly as possible in a rough way. According to Campbell's system, the ground must be worked after every rain, and this is the only way to conserve moisture. Some farmers who are living in the Lower North have for years been working their fallow land according to Campbell's system, with extra good results. Lands here, that have been cultivated for some time, are becoming very much infested with all kinds of weeds, and to get rid of them it is essential that the ground should be thoroughly worked. This will cause all weeds to germinate much more quickly than when the soil lies undisturbed. We should fallow our land as early as possible, harrow same, and as soon as the weeds are growing kill them with a good cultivator. Wheat will pay better than sheep on a farm under 2,000 acres in extent." (Continuing, he stated that the keeping of dairy cows could be combined with wheat-growing, and poultry would add to the revenue. Only good implements should be purchased, and these should be well cared for. Every farmer was advised to keep a small blacksmith's forge on his place. Members generally remarked that there was a marked improvement in the wheat crops and grass lands in the district of late years.

Coomooroo, August 5.

(Average annual rainfall, 12 in.)

PRESENT.—MESSRS. Berryman (chair), Brown, Brice, Fisher, Cooke, H. and L. Avery, W. and M. Robertson, R. Polden (Hon. Sec.), and five visitors.

UTILISATION OF LAND.—The following paper was read by the acting Hon. Secretary :—“Farmers of late years have been doing much to improve the carrying capacity of their farms, but much more can yet be done in the line of intense cultivation. Land-owners should have up-to-date machinery and good shelter for it. They will profit by keeping the best of horses, cattle, and sheep, but they should not overstock. On farms where irrigation can be practised, the growing of peas will more than pay for the trouble. Farmers should pickle the seed wheat and should sow only the best of graded grain. Care should be taken to select varieties which are most suitable for the district. An adequate quantity of hay for all stock for the following year should be stored, and as much straw and cocky chaff as possible should be also saved for dry years. Paddocks of about 100 to 150 acres are a convenient size for sheep, and they will do much better if frequently changed from paddock to paddock. The experiments of the Roseworthy Agricultural College cannot be too closely observed, and I am sure the benefit the State derives from this college cannot be overestimated.” In the discussion which followed, members generally agreed with the views expressed, and thought that the secret of good wheat-growing was in good cultivation. Farmers could not be too strongly advised to sow only the best of graded seed. One member pointed out the expense of fencing small paddocks, but the majority thought the benefits derived would more than compensate the expense.

Cradock, July 27.

(Average annual rainfall, 10½ in.)

PRESENT.—Messrs. M. J. McAuley (chair), P. Neylon, M. Neylon, S. Fitzgerald, A. Clarke, H. Lindo, J. Smyth (Hon. Sec.).

ARTIFICIAL MANURES.—Mr. Fitzgerald had for some time been making experiments with the idea of ascertaining the improvement in crops following the use of different manures, but his experience was that applications made no difference whatever, either in the growth of the plant or yield of wheat. He was of the opinion that there was something wanting in the manures to suit northern soils. [A plan of the experiments would be of great interest. Were the plots carefully measured and the returns weighed to calculate the value of each? An increased yield of a bushel or two per acre cannot be seen in the field, but will often pay handsomely for the extra manure.—ED.]

CO-OPERATIVE SHEEP SHEARING.—The Hon. Secretary read a paper in which he advocated the co-operative shearing of small flocks of sheep. The advantages derived from this system were pointed out, and an interesting discussion followed. Mr. Fitzgerald was of the opinion that if a number of settlers in the district were to combine and erect a shed at a suitable centre, considerable good would follow.

Hookina, August 3.

PRESENT.—Messrs. S. Stone (chair), B. Murphy, P. and T. Kelly, L. Woods, J. Henschke, D. Madigan, and one visitor.

POULTRY ON THE FARM.—Mr. P. Kelly read a short paper on this subject, in the course of which he stated that no farm should be without a number of laying hens. His experience went to prove that the White Leghorn was the most suitable breed for the district. The farmer was well-advised to procure sittings of eggs from those breeders whose strains were successful in the egg-laying competition. The majority of members agreed with the writer of the paper that the White Leghorn was the best breed to keep, but Mr. T. Kelly favored the Minorca, and Mr. B. Murphy preferred the Plymouth Rock.

Morchard, July 27.

(Average annual rainfall, 11½ in.)

PRESENT.—Messrs. W. Toop (chair), R. Jasper, W. Munro, G. Richards, B. S. McCallum (Hon. Sec.), and three visitors.

CARE AND MANAGEMENT OF HORSES.—The following paper was read by Mr. G. Richards :—“Considering that horses are the means by which the farmer obtains his livelihood, he should not mind going to a small expense to provide for his horses' comfort. First and foremost is the provision of a good stable. I believe in a stone stable. As to the roof, different farmers have different ideas. Some prefer straw and others iron.

If I were building I would roof with Wunderlich tiles. These are very little dearer than iron; they are waterproof, have an attractive appearance, and are not loosened by the wind as iron is. They are also warm in winter and cool in summer. The objection most farmers have to iron is that it is hot in the summer time. The best way to keep a stable with an iron roof cool is to ceil it with metal ceiling, and leave a space of, say, 5in. or 6in. between the roof and the ceiling. If this is done, and it is left open, a draught will be caused, and the stable will be found to be always cool. Each horse should have a separate stall; 5ft. is ample width for each. The partitions between the stalls should be made of sufficient height to prevent horses biting one another. At one end there should be a fairly large loosebox. This will be found very useful in which to keep a sick horse. When a horse shows signs of illness, attend to it immediately. A dose of medicine given in the early stages of a malady or disease will sometimes save time and money, and perhaps the horse's life. A medicine-chest should be kept in every stable, as it is too late to go away and buy medicine when the horse is ill. Horses should be well groomed at least once a day, twice, if possible. I once heard it remarked that a horse did not need grooming, because in its wild state it was never groomed. My argument is that a horse in its wild state is never worked and made to sweat, therefore, it does not need grooming; whereas, a working horse's coat becomes caked with sweat and dust. Horses should be supplied with well-fitting harness, which should be kept well oiled, as it is then more comfortable for the horse. Horses should be fed on short feed in preference to long hay. I believe that molasses is one of the best things that a horse can be given when there is no green feed obtainable; it acts as a laxative and also as a tonic to the system. Nearly all the sickness that has been so prevalent during the past two or three months is due to no other cause than want of green feed. A half-starved foal will never make the horse that a well-fed foal will. When breaking in a young horse, never break it down. A horse will prove a more apt pupil if treated firmly but kindly than if it is beaten and knocked about. A horse is like a human being. When a child goes to school for the first time it is not expected to do the same work as a child that has been going several years, but it must be taught little by little. A young horse is the same when it is put in a team for the first time. I believe every young horse should be mouthed and taught to guide before being put in a team. A chain bit coated with rubber is the best bit for mouthing a colt. It can champ this without injuring its mouth. If a horse thinks you are frightened of it, it will try to master you." In discussing the subject, the majority of members agreed that it was necessary to provide suitable stable accommodation for horses.

Quorn, July 27.

(Average annual rainfall, 13½ in.)

PRESENT.—Messrs. R. Thompson (chair), Schulze, Bury, Noll, Cook, Finley, and Patten (Hon. Sec.).

FOXES.—The following paper was read by Mr. Noll:—"Foxes are becoming very numerous, and as they are great thieves of poultry, and will destroy lambs and even weak sheep, they are a great nuisance. The following method of destroying this pest has been tried by a large number of sheepowners and others with marked success:—A number of pieces of bait of sheep's or rabbit's liver, suet, birds of any description, or fish should be obtained, and as much strychnine as may be lifted on the point of a pocket-knife should be placed in each bait. A lesser quantity will kill, but not immediately. Having prepared the bait, wrap it in paper if it is your intention to carry it on horseback. For a drag or trail, sheep's entrails, skinned rabbit, or a stale head will do. The evening is the best time to lay the trail, as the scent will remain about all night. Keep on the open country, and at marked places drop or bury a bait every 300yds. The baits should not be touched with the hand. Any fox coming on the trail will follow it up, and will be found dead within a short distance of the spot where the bait is laid. I prefer birds as baits, as there is not so much danger of poisoning domestic dogs, because they will not touch birds."

Warcowie, August 17.

(Average annual rainfall, 11·94 in.)

PRESENT.—Messrs. T. Donnellan (chair), A. Bairstow, W. and W. E. Sanders, C. Jarvis, P. and J. Duffy, Taylor, Bennett, J. Feineler (Hon. Sec.), and eight visitors.

METHODS OF CULTIVATION.—A discussion took place on the most suitable methods of cultivation for this district. Mr. Telfer thought it a good plan to lightly work the ground

intended for fallow, either during the summer or early in June. Weeds would then grow, and the ground would be in good order for fallowing. It should then be harrowed, and re-harrowed after each rain during the summer, in order to conserve the moisture. Members generally concurred.

Wepowie. July 30.

(Average annual rainfall, 12in.)

PRESENT.—Messrs. J. Crocker (chair), C. Halliday, J. Orrock, G. Roocke, C. Pearce, C. Knauerhase, M. Irvine, J. Chrystall, and one visitor.

TREE-PLANTING.—Mr. C. Knauerhase read the following paper:—"It must be admitted that tree-planting is very much neglected, and whilst the settlers might not at present feel the consequences of their neglect, they will do so in years to come. There will be a shortage of firewood and timber supplies, and shelter in paddocks for horses and stock. Farmers will discover room for hundreds of trees around their holdings on some of the stony land, or in between stone reefs. A clump of sugargums, which are the hardiest of trees, and which will grow where many others fail, should be planted. Around the house also trees should be planted; first a row of the common erect cypress, about 4ft. apart; then two rows of sugargums, 10ft. apart; and on the outside a row of Remarkable pines, 8ft. apart. This will make an excellent windbreak. A few rows of pepper trees and sugargums around the implement sheds and yards will provide excellent shelter. Not only will the trees beautify the homesteads, but they will add value to the property. When preparing for planting, fallow and cultivate the land just as is done for a wheat crop."

Willowie. July 23.

PRESENT.—Messrs. T. Hawke (chair), E. S. Bristow, B. E. Schmidt, A. Stone, J. McCallum, S. C. Greig, and W. P. Foulis (Hon. Sec.).

FARM HORSES FOR THE WILLOWIE DISTRICT.—The following paper was read by Mr. W. P. Foulis:—"In opening a paper on this subject, in the first place we should take into consideration the conditions that obtain here. Our district principally consists of level plain that is moderately easily worked. It is subject to drought, and to years when there is an abundance of green feed in the paddocks. The weather is exceedingly changeable, varying from extreme heat to bitter cold in a very short time. In describing a horse suitable for this district I recognise that it must be one that will breed true to type. Some favor a horse bred from a light mare and a heavy draught stallion. This would necessitate the farmer keeping mares which were not the most suitable. Before confining myself to any particular breed, I will give a few characteristics which, if possessed by any horse, make him suitable for farm work, irrespective of breed. The horse should be what we term a 'good doer,' and a fast walker. These qualities are usually found in an animal possessing the following characteristics:—Compact build, round barrel, well ribbed up, short back, good sloping shoulder, wide and strong across the loins, broad deep chest, moderate to short leg, with clean, strong joints, with plenty of strong, shapely, well-developed muscle, and moderate sized flat bone. I favor the medium draught; not the class termed medium in the saleyards, but that a size or two below our very heavy draughts. They thrive on very much less feed than the heavy draughts, and as a rule travel much faster. In nine cases out of ten the smaller horse will be found in the lead of a team, with the heavy ones in the body. It is easier to breed the medium draught true to the standard I have set than is the case with the heavy draught. The majority of heavy draughts are loosely built, and have a tendency to slab sides and a long back. They are not fast movers, and their own weight is often a burden. They are not nearly so healthy, and cannot stand the strain of fast travelling so well. In a time of drought the medium horse will be found much more profitable. Some will urge that the heavy mare will rear a more profitable foal should the owner wish to sell. Considering the price obtained for the foal only, this may be correct. If sold before three years of age the foal from the medium mare will hold its own; after that age the foal from the heavy mare will probably have the advantage. The price obtained for the foal is not the only consideration. I have lately carefully observed brood mares, and in nearly every case I have noticed that the heavy mares are comparatively poor, whilst the mediums are in better condition. The offspring of the latter are also in better condition. Of course there are exceptions to all rules. For breeding foals for sale I favor mating the medium mares to a heavy draught stallion. It will be found that they will travel faster while carrying the foal, and will work nearer to the time of foaling than the heavier mares.

They will do more work whilst suckling the foal, and do not require nearly so much feed to keep them in condition. A good foal is obtained from the medium mares if mated to a heavy stallion, for it is a well-known fact that the impress of the sire is noticed to a greater degree in the offspring than is the case with the dam. In breeding for farm work, observe the characteristics I have mentioned, and if any are lacking in the mares, see that these are very strong points in the horse. Mate the leggy mares with small barrels to a short-legged large-bodied horse, and low-set mares to a more upstanding horse. Of the various known breeds I favor the Clydesdale of moderate size. This class is exceedingly active, strong, and sound, thrives well, can be depended upon to pull when required, is tractable, and very handsome. In brief, the ideal farm horse is a moderate sized Clydesdale of compact build, round barrel, well ribbed up, good square hind quarters, moderate to short, strong and powerful, yet not with over heavy legs, a fast mover, of good, even temper. It will be noticed that I have mentioned only the heavy and medium draughts. They are the only animals worthy of consideration. The smaller horses and mongrel class contain many splendid animals, and as a whole are a cheap, useful horse for any one commencing farming, but when considering the most suitable horse for the district they are not worthy of discussion. We all admire a uniform class of horse on a farm, and what single class could do the various duties of the farm horse better than the stamp I have described? They can do wagon, van, springdray, plough, harvester, and drill work, and can rear a valuable foal. To make this paper as practical as possible, I will give some measurements of two horses which possess most of the characteristics I have mentioned. The first are those of a four-year-old filly, and are—Height, 15½ hands; girth, 6ft. 5in.; forearm, 23in.; fore cannon, 9in. This filly has good broad square fore and hind quarters, and is, though on the light side, a good class of farm horse. It would be necessary to mate a mare of this stamp to a moderately low-set nuggety stallion. The others are those of a matured horse, and are—Height, 16 hands; girth 6ft. 9in.; forearm, 23in.; cannon, 10in. This stamp of horse is quite heavy enough for our heaviest farm work. As regards hair, I like a fair quantity. It does not help or hinder a horse in his work, but it improves his appearance and is a great advantage when he is put on the market." In discussing the subject Mr. Hawke said the (Clydesdale was undoubtedly the most suitable stamp of horse. No other was so handsome, and activity was characteristic of the breed. Mr. Bristow agreed with the paper. Some thought it a mistake to trot draught stallions, but he believed it did them good, and they should be trotted. Plenty of hair on a horse was an advantage when selling. Mr. B. E. Schmidt said many of the big horses about were the offspring of small stallions, and were clumsy and not true types. Large horses bred from large stock were far more active. It required fewer big horses than smaller ones to do a certain amount of work, but they ate more per horse. He favored the type of horse outlined in the paper. It was weight of body more than size of leg that was required.

Wirrabara, July 27.

(Average annual rainfall, 30in.)

PRESENT.—Messrs. E. J. Stevens (chair), P. Lawson, C. F. H. Borgas, C. Hollett, W. H. Stevens, A. E. Stott, W. Bowman, E. Hollett, S. Thiselton, J. Hollett, C. H. Curnow, W. Marner, J. F. Pitman, P. J. Curnow, A. R. Woodlands (Hon. Sec.).

BROAD BEANS.—In reply to a question, the Hon. Secretary said that broad beans should be sown in good soil early in February, and copiously watered through the spring. Other varieties, such as French beans, should be sown late in spring, and supplied with plenty of water until they reached maturity. He strongly recommended Burpee's Bush Climber for use as haricots.

MIDDLE-NORTH DISTRICT.

(PETERSBURG TO FARRELL'S FLAT.)

Beetaloo Valley, July 22.

PRESENT.—Messrs. A. H. Jacobie (chair), Bartrum, Thyer, Ryan, Bartrum (Hon. Sec.) (GROWING AND STACKING HAY.—The following paper was read by the Hon. Secretary :

—"In dealing with this subject no hard and fast rule can be laid down, as varieties of

wheat which are a success in one district are not always profitable in others. The best wheat for home use in this district is Marshall's No. 3, as it does exceedingly well. For sale purposes I would advise growing King's Early, as this variety is a tall grower, and is about the heaviest hay wheat available. The best time to cut wheaten hay is just after the flower has fallen. The straw will then be white for about 3in. above the bottom knots. This will leave the first part of the stem a bright golden yellow, the balance being a dark green, and sufficient grain will be found in the head. If the area to be dealt with is large, in the last portion of crop cut the grain will be found well advanced. Thus the grower secures both weight and color. To obtain the highest market price hay should be dealt with in this way, and stooked immediately after it has been cut, so that it will keep its color. The greener we can keep the hay the better it will be for market, for as long as the chaff is a good color it will return top price. I have seen beautiful chaff which had been cut on the ripe side condemned, although the grain was nice and plump, whereas with the green hay you would only find a few shrivelled grains. The first mentioned is worth 10s. or 15s. a ton more than the latter, in my opinion; but buyers do not consider this, and will take color before grain every time. Hay cut too green is liable to scour the stock, but when cut at the proper time there is no danger of this. Some farmers prefer oaten hay to wheaten, but I do not consider it to be nearly as good. Oats have to be left till nearly ripe before being cut. If they are cut green the hay is bitter, and stock will not eat it. The argument in favor of oats is the corn for feeding purposes; but I consider what is gained in corn is lost in the straw. The great secret in cutting good hay is to see that the machines are in thorough working order. Cutting should be commenced a day too soon rather than two days late, as is often the case. A hot windy day at the time of the year when the crop is ready to cut will take 4cwt. or 5cwt. to the acre out of it. Hay land should be rolled, as it can then be cut close and the yield per acre considerably increased. For quick carting I prefer the stooks four sheaves deep, two in the centre, and one on either side, bringing the heads to a sloping position. This will stand a heavy fall of rain without damage. To make a success of this method it must be done with the hands. The two end sheaves must be well closed in, to prevent the wind overturning them. When the hay has to remain in the fields for a time, the round stooks are preferable, but care must be taken not to make them too large, or in case of rain a greater portion of the middle sheaves will go black, as the air cannot get at them. Stacking can be started 12 or 14 days after cutting. This, of course, depends on the weather at the time of cutting. If the cutting is done in hot, windy weather, the hay will be ready for carting much sooner than that cut in mild, damp weather. We are, of course, all anxious to get it into the stack as soon as possible, but often tons of hay are spoilt through being stacked too soon. All stacks should be placed on a good bed of straw, of about 1ft. or 18in. deep. Sheaves should be placed butt out, keeping the middle about 3ft. above the sides. This will give the sheaf a good dip, so that the rain will not run into the middle of the stack. I believe in stacking with the fork. Some stack the first two or three rows with the hands, and then fill in the middle with the fork. The difficulty with this is that the stack does not settle evenly, thus allowing the rain to run into the centre. All stacks should have a good covering of straw, either loose or in sheaves, if put on properly. A little time and trouble expended in this way will pay for itself thrice over during a wet winter." In discussing the subject Mr. Ryan said dunnage was better than straw for putting under a stack, as less loss was experienced with the former. The dunnage could also be used for a number of years. Garter oats were the best for hay. The majority of members thought oaten hay preferable to wheaten, so long as it was fed as chaff; but it was usually too coarse to be fed long.

Beetaloo Valley, August 22.

PRESENT.—MRS. A. H. Jacobie (chair), Bartrum, Ryan, Woolford, Burton, Curtin, C. Cox, F. Bartrum (Hon. Sec.), and one visitor.

CAPABILITIES OF THE DISTRICT.—This subject was dealt with in a paper by Mr. J. Burton, in which he stated that when the land in the district was cleared of stone and timber good crops of wheat could be grown. Barley and oats were also to be profitably cultivated, and malting varieties of the former were being tried and gave every indication of success. Lucerne did not receive due attention. The carting of firewood and burning of lime were profitable side lines to which the farmer could direct his attention. Apiculture was making headway, and the cultivation of apples, oranges, peaches, apricots, and nectarines was going ahead by leaps and bounds. There was a large area of land suitable for currant growing, and no doubt this would be utilised eventually. Members generally agreed with the ideas expressed in the paper.

Crystal Brook, July 27.

(Average annual rainfall, 15in.)

PRESENT.—Messrs. M. P. Pavy (chair), W. J. Venning, R. R. Shaw, J. Pridham, B. Flavel, G. Miell, R. Heaslip, J. Teakle, G. A. Solomon, G. and V. H. Sargent, W. Jasper, W. Hutchison, H. Billingham, W. Carmichael, J. Forgan, W. W. Lovelock, T. L. Kelly, R. Pavy, B. Weston, G. Davidson, J. Duffield, E. and W. W. Robinson (Hon. Sec.).

SUCCESS IN FARMING.—Mr. J. Teakle read the following paper on this subject:—

“If we are to make farming pay, we must look to it as a business man looks after his business. It depends very largely on the man himself. We will not find two men who work exactly alike, yet we can and we do take lessons from one another. One of the most important items connected with farming is fallow. Where it can be done, I like to start summer ploughing. On the Gulgare Plains this year several hundreds of acres were ploughed up before seeding. As soon as we have finished tilling we should put the cultivator over the land, and the more work it gets the better. It does not do to work it dry, however. I have noticed that summer fallow turns out well during dry seasons. I am a strong believer in the harrows. I contend that they give the cultivator a better chance. When fallowing it is not wise to plough too deeply; 4in. to 5in. is enough, whether it is ploughed before or after seeding. I almost spoil a piece of land on one occasion by ploughing it too deeply. It was a piece of sandy land with a clay bottom. I turned the clay up on top. I found that this land needed different treatment from the heavy land. I do not think we can get the heavy land too firm, and the looser we can keep the other the better. To grow crops we must fallow, and the earlier the better. Put all the work possible into it. Every farmer should raise his own horses. We have a good selection to choose from now, and it costs no more to keep a good horse than a poor one. It is very gratifying to see how we have got our stock to such perfection, and we ought to get the best to suit our taste. My own fancy horse is the Clydesdale. I have sold two young stallions of this breed from a good roomy mare, and they are doing splendidly to-day. To make a success of farming the best wheats must be grown. For hay purposes we cannot do better than sow Gluyas, King's Early, Marshall's No. 3, and Majestic. I believe the farmers in this district grow Carmichael's Eclipso extensively for wheat. I have found in the Gulgare district that Federation has been the most prolific. It is difficult to say which is the best, but we should select the best, and have it clean. It is a good plan to change the seed for some from another district. It does not pay to plant one variety only. Sheep are of immense benefit to the farmer. I like a good Merino ewe, 6-tooth to a full mouth, for lamb-raising purposes. It is a great mistake to overstock. The most profitable lamb to me has been the crossbred. With 100 good Merino ewes and two Lincoln rams the results should be satisfactory. Some prefer the Shropshire, but both the crossbred and the Shropshire lambs are difficult to keep inside the fences. If we can grow a lamb fit for market in five months and get 10s. for it, it pays well, and every farmer should grow his own meat. Sheep help to keep the fallow clean. A flock of sheep on a farm pays better than too many horses. Whatever the breed of sheep kept, keep the best, as they cost no more. It is not profitable to keep a lot of cows when we have sheep. Two good cows are sufficient; but of course it depends on the extent of the farm. Phosphates have played an important part in our success as producers and tillers of the soil. They are especially helpful during the winter, when they act as a feeder to the plants. Whilst the phosphates force the plant, there is a danger of the hay becoming less sweet, and if they affect the hay, I fancy they must also affect the flour. I believe in growing oats for the horses, and have had some fine crops off stubble land. Oats do not take so much strength out of the land as is the case with wheat. I prefer the Algerian, as they are the most hardy, especially in land subject to takeall. Fowls are also a good paying stock, and I believe with proper management we can have eggs all the year round. Whilst our success in farming depends largely upon ourselves, we must not lose sight of the fact that we also depend on somebody to buy our products. We may have the best land and make every necessary provision, but we must have the rain.” Mr. Heaslip, in discussing the paper, said the depth to fallow depended on the class of soil, some soils allowing of deeper ploughing than others. It was inadvisable to bring a clayey subsoil to the surface. The best variety of wheat to grow differed in different districts, and a wheat which was a success in one district was frequently practically a failure under other climatic conditions. With an early season lamb-raising was very profitable, but when feed was late the opposite was the case. He agreed with the writer that the Clydesdale breed of horses was the most suitable for farm work. Mr. Venning agreed that harrowing was not carried out as much as it should be. Summer fallowing was all right providing the land contained sufficient moisture to enable it to be done properly. The depth of fallow depended upon the class of soil

under cultivation. From his experience, and also on the authority of such old identities as Messrs. Binney and Pavy, he would recommend shallow rather than deep fallowing in this district. He had found the most profitable horse to breed was the short animal, which would do a lot of work and not eat too much. Mr. Flavel considered that 4in. or 5in. deep was sufficient to plough for this district. Summer fallowing had been tried by Mr. Nicholls, who had not found it a success. Mr. Pavy said if summer fallow meant ploughing the land dry, he was opposed to it. When he first came to the North he was in favor of deep ploughing. He ploughed a piece of land to a depth of 7in., and it proved a complete failure as compared with land worked shallower. The most suitable horse for farm work in his opinion was the cross of the roadster with the Clydesdale. Mr. Birks was strongly in favor of fallowing, which could not be done too early. If one could not get on with seeding operations he would advise fallowing as much as possible. He favored the Clydesdale as an all-round horse. The depth of ploughing could best be gauged by experience. Mr. Shearer had found that super. returned good results in the drier districts. Federation wheat had proved a failure, so far as his experience had gone. It was subject to all the diseases by which wheat was attacked.

Gladstone, August 24.

PRESENT.—Messrs. R. E. Lines (chair), J. H. Sargent, W. Brayley, W. Sargent, P. Sampson, T. Mutter, F. Mutter, R. Peters, J. Connolly, T. Brown, G. Black, B. Smalla-combe, E. Davies, S. Masters, R. Coe, J. Eley, G. Fisher, J. Fisher, A. E. Dinning (Hon. Sec.), and six visitors.

PREPARATIONS FOR SEEDING.—In a paper on this subject Mr. J. H. Sargent said fallowing should be begun as soon as possible after seeding was finished. The depth of ploughing necessary was from 3in. to 4in., but where red land was being treated from 4in. to 5in. was advisable. Shallow ploughing kept the moisture nearer the surface and did not take so much working down as was the case with deeper ploughing. All the fallowing should be completed by the end of August, and it should then be harrowed immediately. While it was necessary to do the work as expeditiously as possible, working when the ground was too wet resulted in its being bogged, and working when too dry was responsible for a lumpy upturn. The cultivator could be used for destroying weeds in October, but during the summer months the fallow should not be touched. May was the best month for seeding, but sowing should not be attempted before a fall of rain, and the cultivator should precede the drill over the land. One inch was plenty deep enough to bury the seed. After the drilling following with light harrows was advisable, but not before rain, as there was a danger of causing the seed to malt. Attention was drawn to the fact that various manures applied by South Australian farmers did not in all cases suit the particular class of soil, and knowledge of the constituents of the manures was essential to the agriculturist. A good discussion followed. Mr. Lines favored deep sowing, as it protected the seed and brought it to maturity better. Mr. Peters thought the depth of sowing depended on the season. Mr. Sargent said that wheat could be advantageously harrowed for some time after germination. Several members recommended the use of different manures in successive seasons. The soil could be overfed in the particular constituents supplied by one kind of manure. In reply to Mr. T. Mutter, who considered summer fallowing was advantageous, Mr. Sargent advocated leaving the land untouched in summer and finishing all fallowing by the end of August.

Leighton, July 25.

PRESENT.—Messrs. T. Goodridge (chair), J. Hogan, M. Hogan, G. Pryde, R. McWaters, R. Fairchild, J. Goodridge, A. E. McWaters (Hon. Sec.), and five visitors.

TELLING THE AGE OF THE HORSE.—The following paper was read by the Hon. Secretary:—"Though it is quite common to meet men who profess to be able to tell accurately the age of horses up to a late period in life, nevertheless it is safest for a person not to claim to be able to read a horse's age with accuracy after the animal has passed eight years or so. I do not propose to deal with the construction of the teeth, but to deal briefly with the general arrangement of the teeth, and the ages at which they appear, which, in the case of milk teeth, are shed and replaced by others. A foal at birth has three molars or grinding teeth just through the gums on both sides of the upper and lower jaws. It generally has no incisors or front teeth, but the gums are inflamed, and evidently

upon the eve of bursting. The molars, or grinders, are as yet unflattened. Between one and two weeks old the four central milk teeth appear. At six weeks old the two pairs of laterals appear; the foal has now 20 teeth. At six months the front edges of the centrals and laterals are worn level. At nine months old the four corner milk teeth are through, and the foal has 24 milk teeth. At one year old the first permanent teeth appear. These are the fourth molars or grinders, and the colt will have 24 milk teeth and four grinders. At 16 months, the edges of the milk incisors are level, and those of the top jaw are in contact with those of the lower jaw. At 20 months the fifth permanent molars, four in number, are through. The colt has now eight permanent molars and 24 milk teeth. At two years the corner incisors have lost their marks. At two and a half years the colt sheds his four central incisors, and these are replaced by four permanent incisors. At this period he also sheds eight milk molars, the first and second molars of both jaws, which are replaced by others. At three years the middle centrals are in wear. At three and a half years he sheds his laterals, and also the third molars. At four years the laterals are up level, and the sixth permanent molars are through. The colt has now 24 permanent molars, eight permanent incisors, and four corner milk incisors. Also the tusks generally appear at this stage. At four and a half years he sheds his corner incisors, and they are replaced by permanent incisors. At five his teeth are all level. At six the cups are large in the corner teeth of the lower jaw, small in the lateral teeth, and still smaller in centrals. At seven years the cups leave the central teeth and at eight years old the cups leave the laterals. When the animal reaches the age of nine years, the cups leave the corner teeth, and at 10 years a dark groove will appear in the centre of the corner tooth of the upper jaw. At 15 the dark groove will be half-way down the tooth, and at 20 it will be to the bottom."

Mount Bryan, July 29.

(Average annual rainfall, 15½ in.)

PRESENT.—Messrs. J. Tralaggan (chair), Wardle, Hatherly, Schmidt, E. K. Collins Stewart, Nutt, H. L. Hatherly (Hon. Sec.), and one visitor.

CARE OF FARM IMPLEMENTS.—In a paper on this subject the Hon. Secretary said that it was unnecessary to remind the careful farmer that implements for which high prices were paid should receive due attention; but still the carelessness of some in this regard was astonishing. Machines such as strippers, harvesters, binders, &c., should receive a good coat of paint at least once in two years. This not only improved the look of the machine, but preserved the wood and prevented it warping and cracking. For an implement shed stone walls and an iron roof were most serviceable, and there was less danger of fire than was the case where thatched sheds were used. As soon as an implement was finished with for the season, it should be thoroughly cleaned and overhauled, and then put away. Fowls should be kept out of the implement shed.

Port Germein, July 6.

(Average annual rainfall, 12 in.)

PRESENT.—Messrs. Carmichael (chair), Hacket, Head, Hillam, Stone, Teasdale, Crittenden, Glasson, Blesing, and Turner.

NOXIOUS WEEDS.—The following paper was read by Mr. Hillam:—"The Advisory Board of Agriculture has recommended that the Government take drastic measures to enforce the Noxious Weeds Act, that landholders be compelled to destroy all noxious weeds, and that the administration of legislation be taken out of the hands of district councils. I would like to point out a few facts that probably the general public, more especially southern landholders, are not aware of. Many weeds now classed as noxious, and placed on the list by past Governments through representations from well-meaning but inexperienced and untravelled persons, are not noxious by any means. No weed that stock will live and thrive on should be classed as universally noxious. The Balaklava Branch claims that Salvation Jane, wild turnip, stinkwort, artichoke, and wild onion are noxious; but I cannot agree, as most are fodder plants, and the first-named a good one. Stinkwort in certain stages of its growth is not good, but, like artichoke, comes in very useful at certain times of the year. The ordinary or so-called star thistle, which is not the true star thistle, is classed as noxious by many, and by others as good feed for sheep. It is growing over a great extent of this State and also many of the other States of the

Commonwealth, and the question comes in, is it practicable or possible to eradicate the star thistle, as well as many other weeds classed as noxious under the Act? It would appear to most thinking people that before the Government take the drastic measures proposed they should first find out from persons best qualified to judge if it is really practicable or possible to eradicate them. The trouble is that the star thistle, like many other weeds, was allowed to spread all over the State before being placed on the list. It starts to grow early in the winter, and it is difficult to see until it runs up to flower. Before the district council can give the necessary notice the plant is in flower, and the seeds will mature, and if cut, grow. Many landholders do their best to keep them from seeding, but if the season suits the growth of the plant many will seed and come again as soon as conditions are favorable; and the consequence is landholders when summoned, knowing the impossibility of eradicating the weed, pay the fine as the only way out of the difficulty. The northern councils are well-stocked with star thistle from what can be termed waste lands of the Crown, viz., pastoral leases and travelling stock routes in the northern part of the State, some portions of which are still out of district council areas. The result is that travelling stock carried the seeds from north to south right through the State, and floodwaters carried the seeds from stock tracks east, west, north, and south. If the Government carry out the measures proposed the result will be that all waste lands of the Crown, including travelling stock routes, will be handed back to the Government control, whose duty it will then be to exterminate the noxious weeds. I claim, from personal knowledge of the country and the efforts put forward both by private landholders and district councils, that it is waste of time and money to attempt to eradicate the star thistle and many other weeds gazetted as noxious; and I venture to say if the measures now proposed are given effect to it will spell ruination to hundreds of landholders, who, through no fault of their own, have noxious weeds, especially star thistle, growing on their land. In concluding these remarks, I would suggest that the Government retain a portion of their rough repurchased land infested with star thistle and try the experiment, and keep an account of the cost of eradicating the thistle before taking the extreme measures now proposed." Members unanimously agreed that the star thistle was a great nuisance, but it was utterly impossible to eradicate it, especially in stony and hilly country. It was suggested that before any drastic action was taken the Government should experiment on a rough and infected piece of country.

Port Germein, August 9.

(Average annual rainfall, 12in.)

PRESENT.—Messrs. Carmichael (chair), Crittenden, Head, McDougall, Hacket, Holman, Deer, Hillam, Stone, Glasson, Blessing, Turner, and Stock (Hon. Sec.).

IRRIGATION IN HUNDREDS OF BAROOTA AND TELOWIE.—The following paper was read by Mr. Hacket:—"Not being an expert in this matter it is with diffidence I approach it; but, from seeing the benefit that follows a flood high enough to inundate the surrounding country, it appears to me that a discussion on the possible utilisation of waters situate from 500ft. to 1,000ft. higher than the ground level here might not prove altogether unprofitable. Starting first with Baroota Creek. My opinion is that 500 acres could easily be irrigated from its surplus waters by giving water to different users at alternate seasons. For instance, one landholder could have water this year in summer and in autumn next year, and so on, the one getting the summer supply to receive a greater amount. This would apply to the lower stream. I would say that one-third or one-half of the water-fall's supply diverted ought to give enough water to irrigate blocks of 30 acres for gardens on the foothill slopes. Next in importance comes Boek Creek. Though not nearly so large as Baroota Creek, it would irrigate nearly, if not quite, as much land owing to its greater fall and swifter flow. I am going on the assumption that, say, 12in. of water put on the land at any season of the year is payable. Next comes Telowie Creek. Although it is reputed to be an indifferent supply, a considerable amount of land could be irrigated from it; enough to at least on each farm provide fodder to mitigate in some considerable measure the severity of seasons such as we have just passed through. Broad Creek could also be utilised; and I believe the tapping of both it and Telowie Creek would go to show that the drain on them would improve the quantity of the flow. The only expense ought to be for pipes, as all the waters are high enough to be economically tapped without costly and elaborate head works. I notice that the Victorian compulsory rate is 5s. per acre per annum for one acre foot of water, and I fancy their irrigation works are on a costly scale. I can see no reason why the modest outlay needed here should not, on the same terms, be much more remunerative to the owners of the works. I note one who travelled

through 12 States in America, declared that 10 of them owed their prosperity to irrigation, and also recorded his conviction that the Darling River alone, if used for irrigating, would support all the stock in Australasia. I am convinced that irrigation, on however small a scale, must prove to be a profitable investment." In discussing the subject members generally agreed that beneficial results would follow the damming of the floodwaters referred to, but the spring water was too highly charged with mineral substances to be of much value for irrigation.

BREAKING FARM HORSES.—Mr. Stone contributed the following paper:—"In such a country as South Australia, where farm horses play such an important part, a little may be said about the breaking in of the young draught animal. Most of us have some old-fashioned way of our own, but at the same time there are new methods and ideas that often come useful when handling a young horse. First of all, I would not advise breaking before the animal is about three years of age, as when broken too young the youngster is often broken down. The best time is between August and November, while the green feed is about. When the colt is run in to be caught it is not necessary to get into the yard with about 60ft. or 100ft. of rope. I find a crush pen very handy (or a narrow stall will answer the same purpose), as one can run the colt in and get alongside it quietly; then a headstall can be worked on and a bit put on with two small straps. A surcingle or leather roller should next be placed on and a rein fixed from the bit on to the roller on both sides. The colt may then be let out into a yard for a few hours, after which it may be unharnessed and left until the following day. The next point should be to teach it to lead, which may be managed by placing reins through the two rings of the bit, with a loop left long enough to go around the animal's hindquarters. A knot should be placed in the rope, just behind the animal's wither, then the person leading should pull lightly on the rein on the side on which the animal may happen to have its hind leg extended backwards. Some will lead very quickly by this method. If by this time the animal seems to be of a quiet nature, it may be placed between two quiet horses, and if no trouble is experienced with it here it may be considered fit for the team."

Port Pirie, August 8.

(Average annual rainfall, 12½ in.)

PRESENT.—Messrs. J. Greig (chair), T. B. Jose, E. J. Eagle, C. E. Birks, H. F. Richter, H. G. Hawkins, W. Munday, D. L. McEwin, T. Johns, F. A. Johns, A. M. Lawrie, H. Lawrie, A. Bond, W. R. Wright (Hon. Sec.), and one visitor.

LICE ON SHEEP.—Mr. Birks, in referring to lice on sheep, said that it was likely to become a serious matter with sheepowners. The trouble was largely due to the distribution of lice-infected rams throughout the country. If the rams were dipped before being sold in Adelaide it would be to some extent minimised. Mr. Munday thought it somewhat of a hardship to compel owners of clean flocks to go to the trouble and expense of dipping their sheep. Mr. Hawkins moved—"That this meeting is desirous that stringent measures be taken to prevent the spread of stock pests, such as lice, tick, &c., and that all rams be dipped before being distributed throughout the country." Mr. T. Johns seconded the motion, which was unanimously carried.

CARE AND BREAKING OF HORSES.—The following paper was read by Mr. A. M. Lawrie:—"It is the farmer's duty to see that everything possible is done for the care and benefit of his stock. Horses should have a good, warm, clean stable, with a fair-sized yard. They should be fed regularly when there are not sufficient natural grasses for them. It is a bad plan to put more chaff in the manger or feed-box than will be readily eaten up. Any left soon becomes sour, and, if eaten, is injurious to the horses. The water-trough should be placed so that the horses can drink when they choose. Each horse should have its own harness, and the collars and hames should fit properly. Horses should be groomed at least once a day. A colt should be from two to three years old before it is handled. I prefer to rope them as quietly as possible in the yard. Let the colt see that you are master, and get on friendly terms as soon as possible. As soon as the animal will guide properly, put the harness on and hitch it on to a log and drive it around for a while. Then put it between a couple of quiet horses, after which it can be put straight into the harrows, or any other light working implement. Colts should not be worked long at a time for the first few days until the shoulders get set." Mr. T. Johns was not in favor of horses being allowed free access to the water trough, and did not believe in hooking a colt to a log, as there was a liability of the animal being ruined by an accident. Mr. Munday

said that roomy yards were to be seen on many farms, but clean stables seldom. It would pay to erect an extra stable for the purpose of having a dry place for the horses to lie down in at night. Horses should be allowed to drink whenever they felt inclined, no matter whether they were hot or cold. Foals should not be petted when young; they were better left alone until they were "handled." There was a possibility of injuring a colt by harnessing it to a log. Mr. Richter favored having the water trough placed some distance away from the yard. He would not put a colt in a breast team to teach it to pull, as it generally expected the other horses to pull for it. A good plan was to place a set of single harness on the colt and fix the breeching straps to the collar or traces, so that the weight of the collar could be felt on the shoulders. Mr. Eagle's horses had always been allowed access to the water trough in the yard; by having it there much trouble was saved in taking the horses to water. Mr. F. A. Johns would have the trough in an outside yard, away from the stable. There was a danger in putting a colt in a breast team at first, and it should be well handled before being hitched to a log. Mr. Hawkins generally put his young horses straight into the team and let them take their chance. Mr. H. Lawrie did not like the idea of making a colt haul a log about. He generally considered the animal broken in when he put the blinkers on it, and his horses nearly always turned out to be good workers. Mr. Birks always had the trough in the stable, and no harm had come to his horses. He had put brick floors in six stalls and they had answered admirably. He was satisfied that it would pay handsomely to bed the horses down and have the stalls cleaned out each morning. The manure would also be of more value if heaped up straight away. He would handle foals as soon as he could get hold of them. There was no set rule as to the method of breaking colts, as the temperaments of the animals differed so much. The Chairman would handle the animals well before making them haul a log. He would let them feel the chains on their legs, and if they wanted to kick he would let them do so. They would soon stop kicking when they found that they could not strike anything.

Whyte-Yarcowie, July 29.

(Average annual rainfall, 13½ in.)

PRESENT.—Messrs. J. E. Hunt (chair), Ward, Lock, G. D. J. R., and W. Mudge, Faulkner, Robinson, F. Hunt, McLeod, McGregor, Travers, E. J. Pearce, and F. Pearce (Hon. Sec.).

SOME UNREALISED POSSIBILITIES OF PRODUCTION.—Mr. E. J. Pearce drew attention to the lesson such a season as the present should teach, viz., that of making provision in every possible way to increase the supply of fodder for stock. No proper attempt had been made in the North to grow those varieties of lucerne which were doubtless more drought-resisting than others. Strawstacks were valuable as a shelter, and also as a food in very cold weather. The food value of straw would be greatly increased if lucerne were sown with the wheat and cut with the straw. There was always the possibility of irrigation on a small scale on most of the farms. On some farms there were splendid catchments to provide large dams or small reservoirs; but, for want of these, millions of gallons of water ran to waste annually. He advised the excavation of deep dams in order to overcome, as far as possible, the loss by evaporation. They should be fenced, to keep away stock, and the water should be pumped or drawn out with a syphon. The Government could greatly assist producers by procuring up-to-date excavating machinery, and letting it out on hire, with an expert in charge. Underground supplies could, in some cases, be utilised in the same manner. In some of the northern townships small plots of about a square chain in area had produced feed for a cow and pony. This was done with the aid of a well and small windmill. He advised members to experiment with different varieties of seed, various systems of cultivation, and different times of sowing, in order to prove whether lucerne could not be made a profitable adjunct to wheat-growing. Members generally were of the opinion that no serious attempt had been made at lucerne-growing in this district. Mr. Ward said that some 20 years ago they had sown lucerne on their farm near Ulooloo, drilling it in with the aid of a bottle with a small hole in the cork. In one year they took five cuttings off the plot with the binder, and they sold £50 worth of lucerne. For two or three years the lucerne gave satisfactory results, and then died out, which he attributed to the rise of the spring water, which was close to the surface. He had found lucerne hay difficult to preserve owing to the fleshy nature of the plant, but he thought that if stacked with straw in alternate layers that could be overcome.

Yongala Vale, August 17.

(Average annual rainfall, 13½in.)

PRESENT.—Messrs. C. Fowler (chair), F. and H. Miller, T. Battersby, J. Lloyde, W. and G. Edson, E. Cooper, F. Laubsch, W. Keatley, B. Webb, G. H. Jansen (Hon. Sec.), and four visitors.

NATURE STUDY AS RELATED TO FARMING.—The Hon. Secretary read an interesting paper on this subject, in which he contended that although the study of nature, as dealt with in the schools, was necessarily of an elementary character, if followed up by the scholars it would be productive of practical benefit. A better understanding of the subject would enable the agriculturist to more easily cope with the fungoid, insect, and other pests which were the cause of so much trouble.

LOWER-NORTH DISTRICT.

(ADELAIDE TO FARRELL'S FLAT.)

Balaklava, August 10.

(Average annual rainfall, 15½in.)

PRESENT.—Messrs. H. P. Burden (chair), P. Anderson, T. Lally, H. Roberts, J. Spillane, H. Twartz, P. H. Roediger, T. A. Thomas, W. J. Gleeson, H. M. Tuck, R. Goldney, L. P. J. Hoepner, B. R. Banyer (Hon. Sec.), and one visitor.

QUALITY AND WEIGHT OF SUPERPHOSPHATES.—Mr. W. J. Gleeson read a paper on this subject, in which he said he had recently had three samples of superphosphate analysed by the Government Analyst. One was under the standard, one was only standard, and the third was 5 per cent. over. They all recognised that their crops and soils require manures of the best standard to give good results, and they should not leave the very important matter of quality and weight entirely in the hands of the manufacturers. If they got samples of the season's fertilisers analysed and bags weighed it would cause vendors to use more care in getting it up. Next season he intended to see that all his fertilisers were analysed and the bags weighed. He had been told by some farmers that they had used low-grade superphosphate and the results obtained were equally as good as those obtained from the high-grade supers. If that were so they could save 7s. 6d. per ton by using the former. He had tried using varying quantities, from 60lbs. to 100lbs. to the acre, and he found that 70lbs. was about the best quantity for wheat, and would give good results on fallow well worked. Mr. Tuck believed it would be a good plan to have their manures analysed and the quantities weighed. He made a practice of sowing lowt. of superphosphate, which enriched the ground, although perhaps 70lbs. would be sufficient for wheat, but the heavier dressing caused a heavier crop of grass. Mr. Thomas understood that the fertilisers were tested by the Government Analyst in accordance with law. It was a serious matter to lose 5 per cent. or 6 per cent. in the quality of their super. Mr. Goldney believed that on light land a hundredweight or more of superphosphate could be used without much danger of blighting, and the heavier quantity improved the growth of feed in the following year, although there may not be any increased wheat yield. On this class of land lowt. would give better results than 70lbs. Mr. Lally had used practically all kinds of manures, and had found very little difference in the growing crops. He thought the old Lawes super. was the best, though it was a bit sticky. Mr. Hoepner thought 100lbs. better than 70lbs. of super., and though they might not get much better result in the wheat crop they would have it in feed. Mr. Twartz had weighed bags which were 10lbs. short, though perhaps the average shortage on the whole consignment was not more than 1½lbs. Dealers in chaff were compelled to put a certain weight in a bag, and manufacturers of manures should do the same, so that farmers would know what quantities they were using. There should be legislation providing for a certain number of bags to the ton. It was unsatisfactory to pay for

2,240lbs. and only get 2,000lbs. The quantity used per acre depended on the quality of the land. He could sow 100lbs. on his land, but did not think he would get any more feed. Mr. Anderson thought farmers had been fairly well protected by the Government in regard to the standard quality of superphosphate. They had no time to have samples analysed when they received the super. just at seeding time. On some land the quantity of super. used did not seem to make appreciable difference in the crop, whether half or one hundredweight was used, but experience at Roseworthy College had shown that poor land could be made to yield heavily with the use of superphosphate. Mr. Spillane thought the heavier dressing produced the most feed, but for wheat so much super. was not required. Mr. Roediger had used from 100lbs. to 120lbs. of super, on his land, and some land could be more heavily dressed. He had as good results from low grade as from high. He thought bonedust might be used with advantage. It seemed to help the wheat at the end of the season when it was ripening. [If the lower grade super. gives as good results as the higher, it will be cheaper to apply a less quantity of the high grade stuff than to put on the low grade. This will save freight. Careful tests with results weighed and valued are needed, however, before a man can be sure the lesser quantity of super. pays as well as the heavier dressing. The fact should be kept in mind that the heavier dressing tends to keep the land in good heart for future years.—Ed.]

Friedrichswalde, August 17.

PRESENT.—Messrs. P. Goodfellow (chair), J. and F. Heintze, E. Reichelt, F. W. Duldig, F. W. Schutz, J. B. Coombe (Hon. Sec.), and 13 visitors.

BUREAU LIBRARY.—It was decided that each member should contribute a small amount to provide a fund for the purchase of books on agricultural subjects to form a library for the Branch.

SMUT.—In reply to a question as to the cause of smut, the Hon. Secretary stated that the smut spores were usually present in the soil, and on the wheat itself, awaiting opportunity to germinate. For the disease to perform its function it was necessary that the spores should germinate at precisely the same time as the wheat grain. Bearing out this theory was the fact that wheat sown in dry soil was rarely attacked, as the smut spores germinated more quickly than the wheat, and consequently died for lack of a host upon which to feed. Wheat sown in wet soil, owing to quicker germination, was very often affected, even in spite of pickling.

Gawler River, August 23.

(Average annual rainfall, 18in.

PRESENT.—Messrs. W. J. Dawkins (chair), A. J. and F. Bray, H. Dawkins, J. Hillier G. Higgins, C. Leak, J. Hayman, F. W. Roediger, and B. F. Hillier (Hon. Sec.).

ESCUTCHEONS.—Mr. Geo. Higgins dealt with the escutcheon theory in a short paper, as follows :—"The escutcheon consists of the upward growing hair on the thighs and udder of a cow. It commences as low down as the hock on the leg, and from the front of the udder extends upwards to the vulva, stretching out on the thigh in the form of a shield. Three orders of escutcheons are—(1) The flandrinc, consisting of a broad band running up the back of the udder to the vulva; (2) the left flandrinc, being a band half the width of the flandrinc and on the left-hand side; and (3) the selvage, which has a narrower band at the top, but is broad where it commences and runs up to the vulva. As a general rule it may be taken that the higher on the thigh the shield markings extend the longer will the cow keep up her flow of milk, while the broader the markings on the thigh the larger will be the yield. The presence of two ovals of descending hair is a good sign. These are usually found on the udders of the best milkers. Cows with markings about half-way up the udder are usually very good until they are in calf, when the yield of milk at once falls off. This marking is very readily seen and is most reliable. Escutcheons are not confined to cows, but are to be seen on bulls. In purchasing a sire for dairy purposes make sure that he has the markings. The value of the theory is that it enables one to select good animals for the milking herd."

Mallala, August 12.

(Average annual rainfall, 16½ in.)

PRESENT.—Messrs. G. Marshman (chair), J. J. McCabe, W. McCabe, A. Marshman, A. V. Nairn, Jas. Nairn, S. J. Temby, B. Temby, F. A. W. Kouzag, J. C. Curnow, T. H. Worden, and two visitors.

FRUIT-DRYING AT MILDURA.—Mr. E. Griffiths contributed the following paper:—“Formerly there were many more apricots grown in Mildura than is the case to-day. This fruit has gradually given place to the vine. However, apricot-drying is still a fairly large and, just now, a flourishing industry. This year we had nearly 4 tons of dried apricots. To make up that quantity it took approximately 45,000,000 apricots. To describe the process in a few words: The fruit must be taken from the trees just as it is fully ripe. If taken before it is perfectly matured it will only produce an inferior quality of fruit. On the other hand, if it is left until it has reached the squashy stage, it will be a poor grade, owing to its want of shape. From the trees it is taken in buckets to the pitting shed. Pitting is the process of halving and stoning the fruit and putting it out on the trays to dry. The pitting is done by girls who, by a deft use of the knife, cut the apricot clean round the rim of the stone and open the two halves, placing them face upwards upon a wooden tray. The trays are of various sizes, from 2ft. by 3ft. to 3ft. by 6ft., and the halved fruit, to economise space, must be packed as closely as possible upon them. As the trays are filled they are taken to the sulphuring room. Here they are piled on top of each other 20 or 30 high, and treated with sulphur fumes for about four hours. About ½ lb. to 1 lb. of sulphur will do about 40 or 50 trays. When removed from the sulphur house or box, the little cups left by the removal of the stones are full of juice, which quickly dries up when put out in the hot sun. The sulphuring greatly aids in the drying, which, in suitable weather, should take place in from three to five days. The trays are stacked for a day or two before the fruit is removed to sweat boxes, which hold from 10wt. to 1½ cwt. It is then ready for the factory, where it is graded and distributed to all parts of the world. There are four grades and one subgrade, termed 1, 2, 3, and 4 crown, the latter being the best quality. Peaches are treated in the same manner. The variety grown for drying purposes, though a good eating peach, is not as good as other varieties used more generally for that purpose. It is more fleshy, and is a better keeper. It also carries much better. Of course pitting peaches is easier than apricots, as they are much larger. Because of their greater size it takes two or three days longer to dry them. The quantity of peaches dried in Mildura is very small compared with the apricots. Figs are sulphured in the same manner as other fruits. Great care has to be taken in picking them from the trees to see that they are quite ripe. If pulled before the sugar is all in them they are useless for drying purposes; but it does not matter how ripe they are. In some countries they are left till they fall off the trees, and not treated till they have reached a semi-dry state. In picking care must be taken to break them off without removing the little bit of stem they have with them, otherwise they split and break in pieces before the packing is completed. When being submitted to the sulphuring they are packed closely together on the trays and stood on the flower end of the fruit. They take about one week to dry, after which they are sent to the packing company, where they are dipped in a solution of boiling brine, and in a softened condition, are worked out flat with the fingers and placed in the boxes ready for market. Currants are not treated in any particular manner, simply being gathered and dried. Like all dried fruits, they must be thoroughly ripe before being taken from the vines. The old way was to dry them on the trays, but many now are advocating the use of from three to six storey racks, made of wire netting drawn tightly between rows of posts. The currants are carried straight from the vines to the racks or trays, as the case might be. The trays are stacked 20 or 30 high upon each other and left for from nine days to three weeks. When the currants are nearly dry they are put out in the sun upon canvas. In a day or two they are ready to send to the factory. There they are stemmed and graded. The grade is decided by the body and color, also the gloss of the fruit. Some very heavy yields of currants were recorded in Mildura this year. In some instances as high as 3 tons of dried fruit per acre were gathered, valued at £40 per ton net. This would give a return of £120 per acre. Of course these were exceptional yields; but under good conditions currants are great bearers. Sultanias, or seedless raisins, are the most sought after of all the vine products, so far as Mildura is concerned. The vines are very extensively cultivated here, and they produce beautiful raisins. The fruit is taken direct from the vines to the dip. The dipping is done in perforated tins, holding about half an ordinary fruit case. Fruit and tin are dipped into a tank of boiling water containing a percentage of caustic soda. The dipping is for the purpose of cracking the skins of the fruit and hastening the drying. The immersion is only for a second or two, and after the liquid is drained out of the tin the fruit is put on the

trays or rack, as the case may be, to dry. The drying is complete in from three to six days, according to the weather. The color aimed at by all fruitgrowers is a clear amber or golden. Lexias, or pudding raisins, go through a similar process, but being a larger fruit, they take a longer time to dry. Cluster or table raisins are not dipped as Sultanias or Lexias are, but are put out on the trays from the picking tins. It takes from three to four weeks to dry them. Only the best fruit is reserved for that purpose. It must be a uniform size, with the berries large. In conclusion, I would say in reference to drying all fruit, that it is demanded, both in the growers' interest and to satisfy the packing companies, that it should reach the latter in a nice moist condition. It loses weight and deteriorates in value if over-dried."

Northfield, August 6.

(Average annual rainfall, 19in.)

PRESENT.—Messrs. Williams (chair), Rowe, Dall, Kimber, Roeger, Reynolds, E. W. Kelly, Thompson, and Mitchell (Hon. Sec.).

HANDLING AND EXPORTING WHEAT.—The following paper was read by Mr. W. Reynolds:—"As far back in our history as 1834 the editor of *The Times*, in a leading article dealing with the South Australian colonization scheme, said—'We take it for granted that the hope of mercantile profit by exporting wheat to England from such a distance would hardly ever enter into the motive of a sober-minded man.' This was the opinion of many leading business men of the day, but the past has proved their judgment to be at fault. The war with Russia in 1854, followed 10 years later by the Civil War in America, helped in no small way to establish, notwithstanding the high freights for oversea carriage, the Australian market for wheat in the Old World. In the period of our history just mentioned, the Argentine, as a wheat-growing country, was not thought of, and California, on the Pacific side of America, was the only serious rival Australia and New Zealand had to consider; but as all the wheat grown in that country reached the consumer *via* Cape Horn, this country could deal with this competitor on even terms, oversea freights being equal, i.e., from 25s. to 27s. per ton, whereas the charge per ton from Argentine is only 12s., or less than half the amount, giving the latter-named place a big advantage. When it is remembered that the cost of handling grain till it reaches the consumer must be borne by the grower, it at once becomes apparent that if the Australian wheatgrower is to continue to profitably compete with countries so much nearer the markets, his grain must be handled as cheaply as possible. The world's production is about 3,100 million bushels a year, and that of Australia 90 million bushels. These figures make it manifest that the quantity of wheat grown in Australia and available for export can in no way control the price of the commodity under consideration in the world's markets. There are upwards of 30 countries growing wheat for export, under almost as many different conditions. The chief of these are the United States, Canada, Argentine, Russia, and India. The United States and Canada handle all their wheat from the farm to the ship in bulk, at a very small cost when compared with the bag-handling system. Argentine transports from the farm to the seaboard in bags, and ships in bulk, the bags being returned to the grower; the same are refilled many times. California, Russia, excepting far northern Russia, and India, like ourselves, handle all their wheat from the farm to the home markets in bags. The Californian bag contains about 140lbs., the Indian 100lbs., and ours 200lbs. I take the following from a report by Mr. J. M. Sinclair to the Victorian Government, after he had visited the United States and Canada to inquire into the methods adopted by the wheatgrowers of those countries for handling wheat for export:—'Shippers in California stated that the cheapness of the small bag, and the quickness, facility, and economy with which it could be loaded, and the low rate of insurance for these cargoes had prevented them giving the attention to elevators which might otherwise have been given. At the time of my visit to Port Costa loading ships from the warehouse was being done. All the wheat was being weighed before being passed on board. Men provided with hand trucks with large wheels wheeled five bags at a time on a platform scale, behind which a man sat weighing. On arriving on the scale the man wheeling let go the handles of the truck, which tilted slightly forward on to a small block on the centre of the scale which supported the truck and bags in position. The weigher, in an instant, weighed the bags and truck. The man then, without delaying more than a few seconds, passed them off the scale to the man on the ship's side. Here the bags were passed quickly through three pairs of men on to a wooden shoot, down which, into the further end of the hold, flowed a continual stream of bags. The end of the wooden shoot terminated horizon-

tally about 5ft. from the underlying tiers of wheat already stowed. A number of men engaged in stowing seized the bags on the horizontal portion of the shoot, and with a jerk pulled them on their backs and carried and dropped them quickly in their places. The total number of men working in these gangs, including those wheeling, the weigher, those at the top end of the shoot and down in the hold, was 24. Their regular work in loading is from 1,000 to 1,400 bags per hour. The quickness in the men's movements at this work, and also at stacking grain in the warehouse, is most striking. In stacking or lifting, up to 10 bags in height is done by hand, pairs of men standing on ledges lifting at the end of the same bag. With our heavy bags it is impossible to handle grain so quickly and easily. It would have been a distinct gain for Australian farmers in the past had they abandoned their large sacks and gone in for the adoption of a smaller one.' Let the Australian farmer who has grown wheat for, say, five or 10 years, take a pencil and figure up what he has paid out during those periods for bags to send away his grain in, and also ascertain what he obtained for them weighed in with the grain when selling. He will find the total a very considerable sum, quite enough to build him a comfortable home, or pay a large machinery account. Mr. John Matheson, in a report to the Victorian Government, says:—'At country railway stations in the United States there are erected either elevated platforms or elevators for receiving grain in bulk from the farmers' wagons and loading it into trucks. Where platforms are placed they are constructed of strong planks, and are similar to those to be seen at Victorian country stations, but with the floors about 8ft. above rail level, and a railing on each side to prevent horses swerving off. A ramp is also provided at each end, so that the farm wagon can be driven up on to the platform. The wagons used by the farmers are flat-bottomed, without sides or stanchions. On these is placed a removable box about 4ft. deep by 3ft. 6in. wide and of the full length of the wagon, to the floor of which it is fastened by a few strong bolts. In some districts the farmers, instead of boxes, are now using opened topped tanks secured to the floor of the wagon. In these can be placed a hundred bushels of bulk grain. An opening covered by a slide is fitted in the side of the box or tank which, when the wagon is drawn up on the platform, is on an elevation of about 9ft. from the rails, thus giving sufficient fall for the grain, when the slide is drawn, to pass out quickly into a spout and thence into the trucks.' The rate charged by country elevators on the Canadian-Pacific Railway is three-fourths of a penny per bushel for receiving, cleaning, and loading into the cars. Storing in the elevator for 10 days costs $\frac{1}{4}$ d. per bushel. The cost of erecting large terminal elevators is from 9d. to 10d. a bushel on their capacity, and the cost of handling wheat by the large elevators is about one-seventh of a penny per bushel. Backham's pneumatic grain elevators load and discharge about 180 tons per hour. Large vessels are loaded in from one to two days.'

The unanimous opinion of members was that in South Australia the difficulties in the way of handling wheat in bulk were enormous, and the scheme was quite impracticable, except in perhaps two of the ports.

Riverton, August 8.

(Average annual rainfall, 20 $\frac{1}{2}$ in.)

PRESENT.—Messrs. J. P. Schultz (chair), W. Davis, F. Phillips, R. H. Cooper, Alf. Hannaford, J. W. Kelly, W. Stacey, E. A. Gray, A. F. Kemp, E. H. R. Scholz, W. H. Moss, and two visitors.

FALLOWING.—The following paper was read by Mr. W. B. Davis:—'The sooner after seeding fallowing is started the better. The ground should be ploughed well. 'Misses,' or 'pigs troughs' as they are commonly called, leave a hollow in the ground if they are not covered up with the cultivator. The implement should be in thorough order, each plough cutting and turning its full width properly. Sharp shares make the draught a good deal lighter for the horses. Every other year plough at different depths, from 2 $\frac{1}{2}$ in. to 4in. being the usual practice. If there are many such weeds as clover, dandelion, or stinkwort they should be well turned in, to act as manure for the coming crop. Summer fallowing carried out in the months of February and March is very suitable for the black and chocolate soils in this district. The fallow should be harrowed after a good rain. This will give the weeds a chance to grow, and the sheep can be run on it until after seeding, as it grows far more feed than the unploughed ground. Clayey soil should not be ploughed too deeply, as there is a danger of bringing too much clay to the top. Keep it from running together by cultivating during the spring. All fallowing should be finished in this district by about the end of August or the first week in September. It should be

harrowed when the ground is not too wet in the opposite direction to that in which it was ploughed, in order to break the sod. The rubbish will grow quicker, and it will leave a fine tilth for the next application of the cultivator, after which the cultivator harrows should be run over the land. The light harrows may be used throughout the year. Fallow should be harrowed as much as possible, especially after a good rain. Every harrowing means a bushel more to the acre. The finer the top soil is kept the better, as this conserves moisture. The light implements kill nearly all the weeds. Stinkwort is one of the greatest troubles in this district. If it can be killed when it is young there is less trouble in the seeding. A hundred and fifty acres of well-worked fallow are infinitely better than 200 acres badly managed."

Saddleworth, July 19.

(Average annual rainfall, 20in.)

PRESENT.—Messrs. R. G. Townsend (chair), J. H. Frost, W. T. Frost, F. H. Kelly, P. Cornwell, J. Plueckham, W. Scales, P. Manning, F. Snell, R. Rex, J. H. Eckermann, and F. Coleman (Hon. Sec.).

CARE OF HARNESS.—The following paper was read by Mr. F. Coleman:—"Harness, as a rule, receives very little consideration on the farm, being mainly regarded as a provision for creating work for the farm hands on wet days. Little thought is required to convince that the working gear of the now expensive farm horse is an extremely important item; and since the harness in which he works has a great deal to do with his efficiency and value, a few remarks on the necessary care and attention which is required in order to get the longest service from the harness, with the greatest ease and comfort to the working horse, may be acceptable to the meeting. The collar is the most important part of the harness, as upon it the greatest pressure is brought to bear. Collars for heavy horses are either simply rounded at the lower part, or piped to allow of freer action of the windpipe. The piped collars are the most satisfactory, especially on horses with prominent windpipes. Scrupulous care should be exercised in the selection of the collar. Those who have suffered from wearing tight boots, or having chafed heels, can have some conception of the torment to the horse when he has to do heavy toil in badly-fitting harness. Two extremes must be avoided. The collar should not fit too tightly on the whole or any part of the shoulder, and it should not be too large. Chafing is caused by loose fits rubbing over a part, just as large boots chafe the feet. The collar should fit neatly and firmly over the whole of the shoulder. Whether it does this can easily be ascertained by buckling the collar tightly and gently moving it up and down and backwards and forwards until every part has been inspected. The chief seat of injury is the point of the shoulder. This is the most prominent part, and when the collar fits badly most of the pressure is taken by it instead of being distributed over the whole surface. Nothing is so liable to cause injury to the shoulders and prevent the horse exercising his full strength as a flat collar. A well-fitting collar, when new, is roundly stuffed, and fits closely over the shoulder. It possesses a springiness which makes it comfortable; but after a little use the stuffing is compressed, and the inner surface becomes flat. All collars, when in this condition, should therefore be re-stuffed. Collars are lined with serge or leather. The latter material is cool and easy to keep clean, but is liable to crack. This is a drawback for farm horses, therefore I recommend serge lining. Sweat and dirt accumulate on the surface, and should be regularly removed. If allowed to remain a hard condition is produced, which causes chafing. Young horses have tender shoulders, and are liable to chafe, especially in summer. Bathing the shoulders with salt and water hardens the skin and renders it less sensitive to injury. Where galls are already existent on the shoulder it is often a difficult matter to adjust the collar so that the horse can continue work. The best method is to make a depression in the lining, wide and deep enough to prevent the collar bearing on the sore part. Another plan is to fill stockings to form pads, which are stitched above and below the injured parts. In some cases where a horse's shoulders are so badly affected that no collar can be used, wearing a breastplate has been found effective. Fortunately these are extreme cases. Winkers are, I think, in most general use. Some favor the use of the open bridle. The arguments advanced against the use of winkers are that the eyes are enclosed, and become hot and irritated, and that the horse is more easily frightened by anything coming from behind. Horses, especially those used in crowded thoroughfares, are certainly less likely to bolt when worked in bridles. A full vision of everything before and behind is obtained, and the horse is not so easily frightened by anything rushing up suddenly. All drivers know

that a horse is less frightened by an object coming towards him than by one appearing unexpectedly. A further advantage is that if the headgear happens to be rubbed off, the horse using blinkers generally bolts, if possible, while the one wearing the bridle will remain undisturbed. Where teams are worked it is necessary to use blinkers to prevent the horses seeing behind. A lazy horse working with a bridle is constantly watching the driver, and immediately slackens off when the driver's attention is occupied by some other matter. The blinker would improve the value of horses for work under these conditions. Harness perishes very quickly if neglected, but if reasonable care is taken it will last for years. The leather should be kept soft and pliable by using some dressing such as neatsfoot oil. This should be attended to regularly."

YORKE PENINSULA DISTRICT.

(TO BUTE.)

Maitland, August 3.

(Average annual rainfall, 19½ in.)

PRESENT.—Messrs. Smith (chair), Bawden, Heilemann, Hill, A. and E. G. Jarrett, A. Tossell, Wundersitz, and Pritchard (Hon. Sec).

THE BEST PLOUGHSHARE FOR FALLOWING.—In a short paper on this subject Mr. Bawden stated that the flat, broad share left a flat under surface, while the narrow share cut a furrow with the under part somewhat grooved. This was better for the retention of the moisture, and also encouraged the young wheat plants to strike down into the subsoil.

Minlaton, July 26.

(Average annual rainfall, 17 in.)

PRESENT.—Messrs. C. Parsons (chair), J. Martin, S. Vanstone, T. Gilos, E. Correll, H. H. Evans, R. H. McKenzie, J. McKenzie, and five visitors.

BINDERS.—Members agreed that the 7ft. binder was unsuitable as at present made. It should be manufactured stronger in proportion to the width, as in a heavy crop it could not deal with the full cut.

SEEDING AND HARVESTING.—The following paper was read by Mr. E. Correll:—
 "A successful farmer is often spoken of as having a lot of luck, and singularly this so-called luck seems to follow him in most of his operations. I maintain that there is no luck about it, but that a definite system, properly carried out, is the means of his success. The motto 'Anything worth doing is worth doing well,' if carried out, is bound to bring its own reward. As the soils and conditions in this country are so varied, it is necessary for each farmer to find out for himself by intelligent experiment, or by studying the methods of his successful neighbors, how to treat his particular class of country, and then follow up that treatment. The remarks in this paper will apply particularly to such lands as are similar to those of Yorke's Peninsula, having not more than 20 in. of annual rainfall. Where the rainfall is over 20 in. the methods may have to be varied to suit the different conditions. Any farmer can grow a good crop sometimes, but there must be some reason why a man can produce good crops year after year, with often great variations in the season and rainfall. To attain these results it is essential to start at the land intended to be treated as bare fallow, as it is through the medium of good fallow that good results may be looked for. Care should be taken not to plough under quantities of dry grass or straw, unless in wetter districts, where such will readily decay. The ploughing in of dry vegetable matter is one of the most fruitful causes of takeall, which fungus appears

to flourish where this is done. Dry matter will also prevent the soil from forming the good firm seed bed which cereals need. Most observant farmers have noticed that where the horses turn at headlands or corners, the crop is invariably the best in the field; then why not apply the principle to the whole field? A good burn will clear the way for fallowing, and the fallowing should be done at the earliest possible moment after the seeding is finished, ploughing as deeply as the class of country will allow, in deep soils to 6in. or 7in. if possible, and from 3in. to 4½in. in lighter soils where the subsoil is of a soft or rubby nature. Take care to make straight work that will call for complimentary remarks from those who pass by, ploughing round and round the paddock, or piece, and alternately turning the furrow near the fences in and out, so as to always keep the land level. As soon as a piece of sufficient size has been ploughed, harrow down fine, preferably by crossing the plough work. This will remedy any unevenness left by the plough, which, unfortunately, is often worked so as to throw the furrows far from even. Keep all weeds in subjection as soon as they appear with the aid of the skim plough, or other light implement best suited to the requirements of the case. This can be supplemented by giving a few sheep a frequent run to get rid of any stray weeds. On no account allow any to seed, as a great factor towards success is to get rid of all weeds. Just before the summer sets in, or when the last cultivation takes place, allow the fallow to remain as rough as the implement will leave it. It will be found that an uneven surface will not absorb so much heat as a level surface; further, it will retard the pace at which drying winds will pass over it, will prevent drift in a great measure in loose lands, and if a summer rain occurs after harvest, it will break down much more readily if harrowed or cultivated across the previous work. It will be found that good early fallow so treated will have conserved inches of rainfall which will be drawn upon by the coming crop. Do not expect to find the moisture in the first few inches; this will not amount to much, but go down deeper, down even to 15ft. or 20ft., and this varies for each foot of depth from say ½ per cent. at the 15ft. or 20ft. mark, to 3 per cent. or 4 per cent. in the first 3ft. or 4ft., and the total will be such as to make one feel sure of a good return, given anything like a fair season. Do not rush in and sow all the crop if the season opens dry, but get everything ready, such as all stones or stumps picked, manure put through a sieve, and everything possible done, so that one may concentrate all one's effort in getting in the seed when the rain does come in the best possible time. If sown under dry conditions, the ground will not get into that desirable mechanical condition for the growth of a healthy plant; and also great numbers of weeds will come up which cannot afterwards be killed, and these use up the moisture secured at so much labor. Another point: I find it better to use a little more manure and seed, so as to force a quick growth and early maturity, than to sow too early, which often leads to a heavy crop of straw. This having consumed all the moisture, the grain ripens off too quickly, and the crop does not yield in comparison with the wealth of straw. In drilling I prefer going round the piece instead of backward and forward. By so doing the short turning is avoided, more can be got over in a day, the drill can work right up to the cultivator (which should go ahead of the drill), and the crop will ripen all round at the same time, provided the soil is even. This will enable the harvester to get to work a day or two earlier than if one side of a piece is sown a week or more later than the other. The foregoing will apply equally to wheat, oats, or barley on fallow land. For a second crop I find oats or barley the most profitable, both as to grain production and subsequent feed when left out of crop. In the case of oats for hay, the second crop may be sown as early as one cares, but for grain production I think it best to take advantage of any rain that may occur before seed time, and break up the ground intended to be cropped. Harrow or roll down finely, and cultivate with a good implement after weeds have germinated, and drill in at once, the object being to conserve moisture for the use of the planted crop only. I think it desirable to plant fairly deep, with the object of getting the manure well down in the soil, where there will be a better chance of the plant getting it, as it will thus be in moist earth, and more of it will become soluble. If on or near the surface, it only becomes soluble as rains wash it down. The plant will take care of itself, and may be put down 2½in. or 3in. with safety. One may lose a few plants if they are put in deep, but I am of the opinion that the plants that do come through more than compensate for the loss. If one examines a young plant of wheat, oats, or barley three or four days after it has come up, or at a later stage in its development, it will be noticed that a little nodule appears on the plant at that point in the soil where nature has decreed is the proper depth for the permanent roots. The distance between the grain and these permanent roots varies according to the depth of planting. As soon as the upper, or permanent roots are established, the first roots being at too great a depth, and not being any longer required, die. It is here again that the benefit of placing the manure deep occurs. A dense mass of very fine rootlets which form round the plant are led downwards towards the manure, and thus are less

liable to be affected by the scorching influence of the summer. This point can be exemplified by putting a dressing of stable manure, for instance, around a fruit tree, when it will be found that a mass of roots form immediately under the surface, which get scorched in the summer, injuring the tree. It must not be forgotten that the roots of cereals readily penetrate to a depth of from 4ft. to 5ft., and sometimes more, and draw on accumulated moisture by capillary attraction to 15ft. or more, so that it is important to get the roots to work as deeply as nature will allow. Having prepared the ground, the next important question is the seed and its preparation. The greatest care should be taken to either grow, or procure from some reliable grower, pure seed. This should in all cases be graded with the greatest care, so that only the very best is retained. The cracked or small grains will be far less wasted if fed to pigs or poultry than distributed to rot, or produce weakly plants in the field. In the case of wheat, I am firmly convinced that if the seed is taken from a crop that has been well pickled with sulphate of copper (bluestone), and the succeeding crop sown with dry seed, the results will be more than satisfactory; only that which is required for the next season's seed being pickled. This is a practice I have followed up for eight or nine years, and I have been able to produce a sample clean and free from smut. The last time I pickled the bulk of the crop I lost 8bush. per acre thereby. Dry sowing in this district is now becoming fairly general, and I feel sure that if this practice were carried out throughout the State the total yield would average bushels per acre more than at present. However, if dirty seed is sown, there is no hope of reaping a clean crop. It is well known that pickling kills a large percentage of grain, and retards the germination and growth of the whole, often causing it to lose quite a fortnight as compared with the dry-sown plant. It is equally important to grade barley, and oats may be treated similarly if intended for grain. Barley may be pickled every time, as the injury to the plant is not nearly so marked as is the case with wheat, owing to the outer husk or shell protecting the grain. Pickle oats if the variety is liable to take smut. Do not starve the crop for the sake of saving a ton or two of manure. Put on more than a crop will use. It will be fully utilised during the following years. Part of it will be carried feet into the subsoil, and the deeper roots will surely find it. Part of it will be found on your sheep's back, and another part in the carcass. To leave a nice even job I prefer using the harrows after the drill. This implement will shake the earth from the roots of weeds, cover any seed not covered by the drill, and solidify the land, and will finally make the harvesting machines easier to draw, with less bumping. A word with regard to lucerne. I would strongly advocate every farmer to adopt the practice of sowing from 2lbs. to 4lbs. of seed when sowing the last crop before leaving a field out for grazing, mixing the lucerne seed with the wheat, oats, or barley. This will be very little trouble, a trifle of expense per acre, and of immense benefit to the stock-carrying capacity. It will enrich the soil in nitrogen, its deep roots will open up the subsoil, and the succeeding crops will be much benefited. I may remark that I have found lucerne roots 14ft. down from plants only two years old. By following up this practice one can generally cover 50 or 100 or more acres with lucerne seed each year. This will save the haystack and improve the health of stock. While the crops are growing, see that all fences are put in good repair, attend to any improvements needed, and generally put everything in as good order as circumstances will allow. Get all harvesting machinery put in thorough order some weeks before it is actually required. Do not leave it to the last day or two and then complain if your blacksmith is too busy and cannot do the repairs at a moment's notice. Adjust the harvester or winnower so that it will make a good clean sample, such as one would feel proud to show to one's neighbor or merchant. Let everyone do the same—it may mean raising the standard $\frac{1}{2}$ lb. or 1lb. per bushel. With respect to the water supply, it will amply repay to lay piping and convey the water to every field. If this is done stock can be placed in the field desired, and, having both food and water, will undoubtedly thrive much better than if obliged to travel some distance and perhaps struggle with others to get a drink at the source of supply. Any young stock can be kept out of the way of the workers if shut up in a watered paddock, and thus assist their owner as well as benefit themselves. Experience has taught me that it is more profitable to grow hay on fallow than as a second crop on wheat land. If sown on fallow a supply of good clean sweet hay can be secured from one-third of the area required to produce a similar quantity of poorer quality owing to the prevalence of poppy, charlock, and other weeds on stubble lands. My practice is to mix bushel for bushel of a good hay wheat (I use 'Corroll No. 7') with Calcutta oats. I set the drills to sow from 35lbs. to 40lbs. of the mixture, and drill twice, going round the piece either with two drills of different width, or working the second time with the centre of the drill over the previous wheel mark. The manure can very well be set at lowt. each time, making a dressing of 2cwt. By this method I have secured crops of from 4 tons to 5 tons per acre during the past three seasons, but only using 1 $\frac{1}{2}$ cwt. of manure. Thick

sowing will give a finer straw and proportionately more grain than thin sowing. As the surveyors on most drills are not reliable, I would strongly advise every drillowner to write on his drill the correct distance such drill will travel to sow an acre. Travel over this distance in the field once and mark the result on the surveyor, and also on the drill lid. It will show what one is doing at any time, and come handy for reference to any new hand taking the drill. The 11-hoe drill will travel $113\frac{1}{2}$ chains for an acre; the 13-hoe drill will travel $94\frac{3}{4}$ chains for an acre; the 15-hoe drill will travel $80\frac{1}{2}$ chains for an acre; the 17-hoe drill will travel $70\frac{1}{2}$ chains for an acre; the 19-hoe drill will travel $62\frac{3}{4}$ chains for an acre. In cutting, take the binder round the piece, and so follow the drills. It will be found that cutting across drills will give a succession of shocks to the binder, due to the knife engaging its full length when over the drill mark and then running empty for 2in. or 3in. before engaging the straw in the next drill. Follow as close as possible after the binder, and stook at once. By so doing the stooks will all dry together, and will stand high winds much better than if allowed to wilt before being handled. If it is desired to stack at the earliest possible moment, put it up in long stooks (four in a set) with an air channel through the centre. If drying winds prevail it may be ready to cart in a week or 10 days. If it cannot be carted for some time, or has to be left till after harvest, put it up in round stooks, not too big, but standing as upright as possible. This will enable it to stand with little injury from sun or rain. When it is very hot, leave the hay alone. If put into the stack dry and brittle, it will come out in the same condition, even in the middle of the following winter. It will be bad to handle, and will break up badly when chaffing. When stacking, place every sheaf with its butt outward, never placing a sheaf lengthwise of the stack, as such sheaves will not pull out when the stack is being taken down. Keep the centre of the stack from 2ft. to 3ft. above the sides from start to finish. Finish with not too steep a roof, and thatch well with straw cut with a binder, securing the same with binder twine from sheaves and Launceston palings split to make suitable pegs." In discussing the subject members did not approve of deep drilling. They were of opinion that all that was necessary was to cover the seed properly.

Pine Forest, July 30.

(Average annual rainfall, 13in.)

PRESENT.—Messrs. D. Carmen (chair), G. Inkster, A. Hewett, A. Nelson, W. Attenborough, S. Barr, C. Schultz, W. Smelt, R. D. Goodridge (Hon. Sec.), and a large number of visitors.

EXPERIMENTAL PLOTS.—The experimental plots being conducted by Mr. Barr were inspected, and it was found that they were doing very well.

ANNUAL MEETING.—On account of this being the annual meeting of the Branch, a social gathering was held in the evening, at which there was an attendance of about 100. The report of the Hon. Secretary was read, and the Secretary to the Advisory Board delivered a lengthy address on the Agricultural Bureau and various other matters of interest to agriculturists.

WESTERN DISTRICT.

Coorabie, August 3.

PRESENT.—Messrs. C. T. Giles (chair), W. H. Wheadon, C. Wheadon, Riddle, Atkins, Murray, Gregory, Kinsley, C. Hobbs, Attick, Woodforde, Cousins, Coppins, Roberts, Underwood, H. V. Hobbs (Hon. Sec.), and one visitor.

FOLLOWING.—Mr. C. T. Giles read the following paper on this subject:—"I strongly recommend following in this district, for several reasons. In the first place there is no

doubt that the yield is greatly increased ; secondly, fallowing is a great help to the farmer in his battle against troublesome weeds and rubbish ; and thirdly, a very important point, it puts forward seeding operations for the succeeding year. The three years' course of feed, fallow, and crop is not practised to any extent in this district, on account of the farmers not having sufficient land cleared ; but if there is sufficient cleared land I would recommend that system. The year that the land is under grass would do much to firm the soil, and thus reduce the liability to drift. When bare fallowing, I would recommend burning the stubble. The plough would destroy the grass much better if the stubble had been already burned. The fire also destroys many weeds. The farmer should regulate the time of fallowing in order to finish before the grass goes to seed. Fallowing should not be commenced too early, as ample time should be given for all weeds and other rubbish to germinate. A saving in the subsequent working is thereby effected. About the end of July or beginning of August is a good time to commence, but the time must be governed by the amount to be done. A plough that cuts all its ground and turns the soil well over should be used. It is a mistake in this district to plough deeply, as the subsoil is so near the surface. Three or four inches is quite enough. Ploughing in showery weather is a waste of time, as it transplants the rubbish you wish to kill. Ample strength for the ploughing should be obtained. It is better to have too much strength than too little. I would work leaders if using more than six horses, as otherwise they are liable to trample on one another's heels when turning the corners. The after working of the fallow can be easily overdone in this district on account of the liability of the land to drift. If the land is kept clean the less working that is done the better. It would pay every farmer to keep sheep, if only for the benefit to the fallow. I would not sow wheat on fallow land before the first seeding rains, unless the season opened unusually late. The moisture which is always to be found in fallow will, in places, be sufficient to cause germination, but in other places it will cause malting." Mr. Kinsley favored ploughing in the stubble in preference to burning it off. The former returned the organic matter to the soil. Mr. Atkins favored fallowing early in order to conserve moisture. Mr. Riddle considered it advisable to commence fallowing directly after seeding, provided the grass had got a good start. The horses were in better working condition at that time than if allowed to run for a month or two on green feed. The months generally favored by members for fallowing in this district were July, August, and September, but not later than September. Mr. Attick preferred the disc plough, as did Mr. Kinsley, in stubble and clear ground, but not in stiff grassy land. Mr. Riddle expressed the opinion that it was worth while cultivating stubble directly after seeding in order to encourage the mustard seed to germinate, so that it could be fallowed in. Members differed in opinion as to the best implement to use for the after workings. Some recommended the skim plough, while other preferred harrows. Members generally agreed that fallow land should be thoroughly worked, whether woody or not, for the benefit of the soil. All members agreed that it paid to keep sheep, and to run them on the fallow occasionally. Mr. Atkins thought that a team of eight horses should be worked in fours. Mr. Riddle preferred working them abreast. Mr. Underwood thought that by working in fours the necks of the back horses would suffer through the draught of the leaders.

HORSES ON THE FARM.—Mr. C. B. Atkins read the following paper on this subject :—
"I prefer the medium draught horse for general farm work in this district, as it is more active and stands the travelling better than the light or very heavy draught. I have both light and medium horses on my farm, and I find it takes no more to feed the larger horse than it does to feed the light, and fewer horses are needed to do the work. I would advise any man beginning farming on a new farm to buy two or three good medium upstanding mares of the Clydesdale class if possible. He will then have a good mare to begin with. Weighty horses are the best in these districts, because good strong horses are necessary for the farmer to get his produce to market over the bad roads. Every farmer should obtain two or three foals every year if possible. He will then be able to replace the aged with the new stock. The Clydesdale is the best sire for this district, as the mares are on the small side. By adopting this course the farmer will be able to breed a larger and better stamp of horse." In the discussion that followed Mr. Kinsley stated that the pure Suffolk Punch was, in his opinion, the ideal farm horse. Mr. Riddle expressed the opinion that if using a Suffolk Punch sire he would only mate him with big heavy mares, and so get a serviceable draught horse. The Hon. Secretary stated that the Suffolk Punch did not cross well with the other breeds of draught horses. Considerable difference of opinion existed as to whether the light or medium draught horses required the more feed when working side by side, but the majority thought that the light horse was the easier to keep in condition.

Elbow Hill, July 27.

PRESENT.—Messrs. Cooper (chair), G. Dunn, J. Rehn, E. Wake, H. Wheeler, S. Wake L. Wheeler, E. Story, A. Wake, A. Chilman, P. Wake, C. Jacobs, G. F. Wake (Hon. Sec.)' and two visitors.

CARE OF FARM HARNESS.—Mr. H. Wheeler read the following paper on this subject :—"Farmers are apt to pay too little attention to their harness, which should be thoroughly overhauled and oiled twice a year. Neatsfoot oil is most suitable for heavy harness, and for light harness Lewis & Whitty's fatblack and polish should be used, as dust does not collect on it as it does on oil. Every horse should have separate collar, hames, and winkers, and should not be worked in any others. The collar should fit the horse, because if too big it is liable to work round on the shoulder and so chafe. If the collar is too small there is always a danger of the horse choking down. Farmers, when buying horses at sales, nearly always buy the harness with them. This is a mistake, as very often it is a misfit. It would pay far better to take the animal to a saddler and try on the collar before buying it. Always hang the collars on a rail when not in use. Frequently they are thrown down in a heap, and so the padding is pressed out of shape. They should not be hung up in the stable beside the horses, as they are likely to be knocked down and trodden on. It pays better to keep all the harness in a separate shed near the stable. In cases of sore shoulders the hames are very often as much at fault as the collar, because if the draught is not in the right place the collar will not set in its proper position. This must be determined by the shape of the shoulder. The hames should fit tightly on the collar. Wagon saddles should always be kept well oiled. When buying a wagon or dray saddle it is advisable to get the largest size, as a small saddle is bad on a horse's back. When working a team carry a few rivets. If a strap breaks it can then be mended immediately without much trouble, and this will very often save much inconvenience." In the discussion that followed Mr. Chilman agreed that it was advisable to have a separate shed for the harness. Mr. E. Wake thought harness should be oiled twice a year. Mr. Rehn said it was a good plan to have a strip of leather on the farm in order to effect repairs. When cutting the leather it was best to cut the whole length, so that a straight side could be had when wanted. Mr. A. Wake contended that each horse's hames should be hung in its stall, so that there would be no mistaking them.

CO-OPERATION AMONGST FARMERS.—The following paper was read by Mr. S. V. Wake :—"In a district such as this, where one farm joins on to a neighboring one, and good roads connect, I maintain that by the co-operation of a limited number of the men on the land they could minimise their expenses in the machinery line and in various other ways. Let us consider the advantages to be derived by the united purchasing of a few lines of machinery. Now the average farmer does not grow sufficient wheat to warrant him buying a motor winnower. If three or four were to club together in the purchase of same, each reaping a portion of his crop with the stripper, and all assisting in manning the machine, they could very soon clean their heaps more thoroughly, saving time, money, and chaff. The latter in many parts of Australia would have been very acceptable during the autumn of this year. I have had enough experience with the hand and horse-power winnowers to judge which is the easier and cheaper way of cleaning wheat, and the motor is far in advance of either. Where we cut hay only for our own use, if properly worked a binder could tie in from eight to 10 days all the hay one would require for the year. This machine is practically idle all the rest of the year, and two farmers could very well manage with one between them. I see from the *Journal* that the members of a certain Branch have procured a seed grader. If others followed the example it would be to their advantage, as well-cleaned seed is necessary to ensure even distribution and proper germination. There are many other cases in which the same system could be adopted. I also wish to draw attention to the breeding of horses. I am in favor of, say, four or five farmers owning between them a good Clydesdale stallion, and keeping him for their use only. The horse could be kept and worked by one. This should ensure a better percentage of foals. Co-operation in rabbit destruction would greatly assist in keeping the pest in check. Branches of our Bureau should work with more enthusiasm and energy than they do now. Several matters of importance referred to our Branches by the Advisory Board for consideration have been neglected. Take the weighing of wheat in bulk, and blocks for farm laborers. Only 45 responded in the case of the former and 34 in the latter, out of 130 Branches. If reforms are to be brought about in matters which concern the producers, we should be alive to our interests, and the Bureau should be the intermediary between the producers and those in authority." In the discussion which followed Mr. Dunn thought co-operation was all right for farmers who were just starting, but when one could afford to buy the machinery he required, it was better for him to do so. He favored the co-operative ownership of a good draught stallion and also

a seed grader. Mr. Chilman said a motor winnower would do for three or four farmers, but Mr. J. Rehn thought it best for every farmer to buy his own machinery, as it was always to hand when wanted, and there would be no disputes with regard to paying for breakages. Mr. E. Wake favored co-operation for the purchase of a seed grader and a draught stallion.

Green Patch, July 29.

(Average annual rainfall, 26in.)

PRESENT.—Messrs. F. Gore (chair), J. Sinclair, sen., J. Sinclair, jun., G. Sinclair, R. Sinclair, E. Chapman, G. Merchant, C. Parker, C. J. Whillas (Hon. Sec.).

SPRAYING FRUIT TREES.—Mr. G. Merchant read the following paper on this subject:—
 “We are free of many of the insect and fungus diseases that are prevalent on the Adelaide side of the Gulf; and here I would sound a note of warning to those who contemplate growing fruit and vegetables. If great care is not exercised we will not be long free from them. I have consistently advocated planting fruit trees, as we have soil and climate to produce fruit for commercial purposes; but care will have to be shown in the management after planting, and watchfulness shown in regard to diseases, either insect or fungoid. It would be a good plan if the Government were to appoint a competent person as a travelling instructor, to show growers how to prepare land, how to plant, to treat and to prune fruit trees, and to detect any disease that might at times gain a footing here. I know the need of such, by the numbers of letters and inquiries that I have had this winter from persons that are about to embark in this enterprise. Curl leaf is a fungus that is only active during the spring months. The spores or seeds remain dormant on the host plant through the other part of the year. This is well known to all growers of the peach on the Adelaide Plains, but not so well known here, as it is only just making its appearance. If we combat it from the first, it will not entail much labor or cost, and will not do much damage. Now the first essential in dealing with disease on tree or plant is the spray pump, and I would advise two or three growers that are near each other to purchase a small plant. It will not cost more than £3, and will last for years if taken care of. The best preventive we have is the Bordeaux mixture, which is composed of lime and bluestone (sulphate of copper), with water. In the case of curl leaf, it is necessary to do the spraying before the disease makes its appearance, as when it appears, all the spraying will be of little avail. When mixing take 4lbs. of copper sulphate and dissolve it in 3galls. or 4galls. of water. This must be done in a wooden or earthenware jar, as it will eat through tin in a very short time. Six pounds of good new lime should be slaked in a kerosine tin with about 2galls. of water. This will make 40galls. of mixture. Half a pound of bluestone will make 5galls. The mixture should be made just before it is intended to apply it. The time to apply is a most important factor. Keep an eye on the peach trees and, just as the buds begin to burst, or just as the pink of the first blossoms appear, apply the mixture. Damp all parts of the tree. Do not put on too much, as being heavy, it will run to the ground. Keep the mixture well stirred to prevent settling. When mixing the limewater with the copper, strain well, and strain again through bagging into the spray pump. There is another disease that has made its appearance in the district, that is black scale. I have seen it in several places on apricot and quince trees. This disease is easy to detect. If any of the trees have a sooty look, examine them well, and brownish and nearly black scales will be found. These scales cover a large number of eggs, which hatch out in the early spring. They are so small that they do not attract any notice, being like small specks of white ashes. If I am not greatly mistaken, we shall suffer for the apathy we are showing at the present time in regard to codlin moth. It is in the district, and, unless we take the matter in hand and deal with it in a drastic manner, we shall suffer in the near future. We should to-day discuss what steps should be taken to eradicate it from the district. What endless labor and expense would have been saved growers on the other side, if the governing bodies had grappled with this disease when it was first found in a few old apple and pear trees in Hackney near a jam factory. A few pounds spent in rooting them out and burning, would have saved thousands to the growers. Other diseases can be treated with the following remedies:—Red spider, sulphur and lime; thrip, tobacco water; scale, kerosine emulsion or red oil.” After the paper was read Mr. Merchant explained the difference between the potato moth and the codlin moth with the aid of colored plates. He emphasized the importance of immediate action to stamp out codlin moth in two old gardens existing in this district.

Miltalie, July 27.

(Average annual rainfall, 14½ in.)

PRESENT.—Messrs. A. R. S. Ramsey (chair), W. G. Smith, H. R. Jacobs, C. E. and S. R. Searle, T. A., A. M., M. H., and P. G. Wilson, J. P., J. W., and E. Story, W. E. Hier, (Hon. Sec.), and three visitors.

SHEEP ON THE FARM.—Mr. H. R. Jacobs read a paper, in which he stated that when the land in this district was subdivided a good income should be derived from sheep. They were unable to take advantage of the export lamb trade owing to the high freight charges. Several farmers essayed a shipment of lambs some time ago, but it did not prove successful. Apart, however, from the fat lamb industry it would pay well to keep sheep. They were of great value in destroying weeds after summer rains when the farmers were busy with harvest operations. It was advisable to keep wool-carrying breeds. The Merino was the best, as the wool returned the highest prices and the sheep themselves could live under more adverse circumstances than was the case with other breeds. For home purposes he preferred a cross with the Shropshire, as these grew more quickly and were a heavier type of sheep. Closely wired fences were necessary for these animals. Sheepskins should be hung lengthwise over a rail in the shade and brushed with weevil wash if kept for any length of time. In the discussion which followed the Hon. Secretary favored the Merino, as it was easy to keep within the fences, grew better wool, and provided good mutton. Mr. J. P. Story said sheep were very useful for cleaning fallow. The Merino was a good breed to begin with. Mr. W. G. Smith did not favor cross-breeds for this district. Skins should be fastened to a frame and properly stretched out. Weevil wash kept dogs and cats from tearing the skins, besides destroying weevils. Mr. R. Smith (a visitor) considered that mixed farming would become a feature in this district. He favored the Merino, because of the market price for fat lambs. Mr. Jacobs, in reply, said his experience had been that wool had brought a better price when the Merino ewes had been crossed with Shropshire rams.

Miltalie, August 24.

(Average annual rainfall, 14½ in.)

PRESENT.—Messrs. A. R. S. Ramsey (chair), J. P., J. W., and E. Story, F., J. S., and H. R. Jacobs, F. F. Alm, W. G. Smith, P. G. and A. M. Wilson, C. E. Searle, W. E. Hier (Hon. Sec.), and two visitors.

FARM LABORERS.—Mr. A. M. Wilson read the following paper on this subject:—"To the farmer without a family the question of labor is an important one. To work his farm properly and profitably he must hire assistance. If the employer were to show more consideration, however, he would experience less difficulty in obtaining this. Hands should be paid the ruling rate of wages. The quarters should be roomy and weather-proof. If the man is hired permanently he should be allowed a fortnight's holiday every year on full pay, and also an occasional half-day. If the laborer is married, it will pay the farmer to build a four-roomed house, and allow his man to keep a cow and poultry. It might be advisable to give the laborer a share in the crop, as the responsibility and interest created would cause him to work in a more thorough and painstaking manner." In the discussion which followed, Mr. J. P. Story and Mr. F. Jacobs both agreed that if farmers considered the comfort of their laborers more there would be less difficulty in obtaining men for farm work. Mr. W. G. Smith thought that it depended on the farmers' means as to the size of the house for married laborers. Mr. J. S. Jacobs favored the share system, and agreed that laborers should be allowed a day off occasionally. Mr. E. Story did not agree to allowing laborers two weeks a year on full pay.

Petina, August 17.

(Average annual rainfall, 12½ in.)

PRESENT.—Messrs. W. Penna (chair), D. T. Kenny, I. Kenny, J. Bascombe, E. Keeley, D. J. Howard, H. Doley, G. Newbon, G. H. Newbon, J. H. Wharf, J. M. Souter (Hon. Sec.), and four visitors.

IMPROVING THE FARM.—Mr. J. H. Wharf contributed the following paper:—"It is quite impossible to lay down any rules or lines of guidance for the man taking up land,

as everything depends on the circumstances of the settler and position of the holding as regards water, roads, &c. Probably all have made mistakes in starting in some way or other. There is, however, one point that most will agree on, and that is economy is absolutely necessary in starting a new place. A new settler is, in my opinion, quite justified in putting improvements that will meet requirements for the time being, even if they are not so stable and substantial as one would expect to find on older settled farms. This applies to fencing, tanks, dwellings, stables, and sheds. The actual farming should, however, be conducted on the best known lines to give the best possible results. As time goes on and the farm is prosperous, the farmer should provide a comfortable dwelling-house with large and lofty rooms, good ventilation, with a fireplace in each room. A capacious tank (with a good iron roof) for domestic purposes is necessary. A comfortable men's room, sheds, barns, and stables should be made with high gable iron roof, with tanks provided for holding the water caught thereby. The farmer who has to depend solely on tanks, seeing that shallow tanks lose so much by evaporation, should provide one or two, say, 10ft. or 12ft., for a stand-by in case of drought. On account of rabbits it is necessary to use a good deal of wire netting. The life of netting in scrub land is about 10 years, and rather more on plain land. The failure of netting to withstand rust is due in a great measure to the fact that it has not been properly tinned when manufactured; probably a bath of gas tar would prevent rusting so quickly. When the netting is too bad to keep rabbits out, and where stones can be had close by, the trench should be opened out and filled up with stones and finished off with a row on each side. This plan is very effective, but takes a lot of time. Iron posts should be used where the rock is close to the surface. Rough and high stumps are a source of worry, being the principal cause of breakages in farm implements. They can be easily dealt with in the dry summer by burning. I have an old sheep trough 8ft. long, mounted on wheels, and drawn by a horse. A fire is made and wood is put in the trough, and coals are placed on the biggest of the stumps." In discussing the subject, Mr. Howard said shallow tanks were less liable to leak than the deeper ones, on account of the less weight of water. Mr. Lewis preferred good sharp sand for cementing, and for the bottom of a tank he would use broken metal. The difficulty in getting tanks to hold in this district was due to the sand not mixing well with the cement.

Utera Plains, July 27.

(Average annual rainfall, 14in.)

PRESENT.—Messrs. P. Sinclair (chair), A. Ramsey, A. Venning, W. Gale, W. Stephens, J. and M. Abrook, H. T. Hornhardt, F. Braunack, G. C. Bilney, M. Hunt, H. Rule, F. H. Haywood, W. Lee, R. Hill (Hon. Sec.), and five visitors.

SOILS.—The following paper was read by Mr. A. Ramsey:—"The soil is a most charming chemical laboratory, where numerous complex chemical changes are constantly taking place. We can scarcely imagine it as teeming with life, microscopic though it be; in fact, more thickly populated than the surface of the earth. For generations and generations the soil and everything connected with it has been shunned. Only during recent years have farming and gardening been considered desirable callings to pursue. The immense strides which have been made in agricultural science have done a great deal to raise the rural industries to a high level. The spirit of investigation has been aroused, and every intelligent farmer is studying his soils and crops, and endeavoring to understand more and more about the farm which he owns. Nothing seems simpler than to make a chemical analysis of a soil and find out what is missing in it that makes it inferior to a soil in another part of the State; but it is not such a simple matter as it looks. The soil is not only a vast reservoir of plant food which can be drawn upon by the roots of plants just as needed, but it is also a great factory where raw material in the shape of manure is formed into the finished article—the crop. A complete knowledge of the soil and the part it plays in the feeding of the plants is only obtained by an investigation into the chemical, physical, and biological aspects of the question. We must not regard the soil as a mere storehouse of plant food. Water is indispensable to all plants. It is, therefore, of paramount importance to study the movement of water through the soil. The texture of the soil and the proportions of water and air which it retains, affects its temperature. Some soils are much warmer than others under the same conditions, hence some soils are early and others late. The soil is not a dead, inert mass. It is a scene of the greatest activity, both chemically and biologically. Were we able to watch the countless operations going on in the first foot of soil we would be filled with wonder and amazement.

Probably, with all our great inventors working on these subjects, we shall some day have presented to us in cinematograph style a busy scene as enacted in our surface soil. Some of the organisms in the soil work upon the dead vegetable matter and completely transform it into valuable plant food. Other organisms work in an opposite direction and destroy the plant foods. Certain other organisms live upon the roots of plants, to the mutual benefit of both. One cannot help noticing that certain plants do better in some regions than others. Some plants grow well near the seashores, whilst others grow to perfection in our very sandy soils. Certain weeds grow well in clay lands, others again tolerate the sandy stretches of country. Plants are much influenced by environment, and at times are slow to adapt themselves to new conditions. This is noticeable with introduced plants. A wheat that does well in Russia or Manitoba may, during its first season, be almost a failure in our State. It may take several years before the new plant accommodates itself to new conditions of life. From what has been stated it must be felt that a thorough knowledge of the soil and its origin is of great importance to the farmer. If we take samples of soils from various sources we notice that they are composed of mingled fragments of different material, chiefly small particles of rock of varying sizes, from small pebbles to grains only discernible by the magnifying glass. From such examination we are led to believe that all soils have been formed from rocks. All soils are derived from the original or igneous rocks of the earth. Granites, diorites, and gabbros are good examples of the primary rocks of our globe. Geology teaches us that our globe was once a molten mass, which, upon cooling, solidified into rocks. These rocks must have contained all the mineral matter of plant food. We can study these changes best by reference to the lava beds of recent origin. In an incredibly short time this molten material solidifies, and the resulting rock is soon transformed into more or less fertile soil. The first step in the formation of soil from rock must be the breaking up of the rock into smaller particles. Quite a number of natural agencies take part in this process. Heat and cold, the action of air, water, ice, and wind, all have their work to perform in this respect. Consider a granite rock. We are all familiar with the granites at various parts of South Australia. Those who have visited Port Lincoln must have been struck with the great development of granite rocks in that district. It is an easy matter to distinguish with the naked eye three distinct minerals which comprise these granite rocks. The black-looking, shining material which peels off in small flakes is mica; the pink mineral is felspar; and the somewhat bluish mineral is quartz. A typical granite contains mica, felspar, and quartz. These three minerals are differently affected by changes of temperature. When heated they expand at different rates, and when cooling their rates of contraction are different. When such rocks are subjected to extremes of temperature the result must be that they are shattered; not, of course, in a single night. The natural forces are continually operating. In our northern districts, and particularly in Central Australia, the difference in temperature between day and night is very marked indeed. At the hottest part of the day a temperature of about 160° is experienced, which gradually sinks to zero at night. The water will almost boil in the day, and at night become frozen. Rocks in these regions are constantly being strained by the unequal expansion and contraction of the component minerals. Even if the rock is composed of only one mineral, these changes of temperature gradually tend to disintegrate it. It can easily be imagined how soon granite rocks begin to crumble away in the dry regions. They are eventually reduced to dust. Then the wind does its part in conveying this dust to other places, piling the material up into vast sandhills or dunes. The great sandy ridges of Central Australia, the dunes of Sahara and Central Asia are formed in this way. There are immense deposits of loess in China. This vast accumulation is supposed by geologists to be nothing else than the fine dust carried by the wind from the great desert of Central Asia. Those who have lived in Broken Hill can readily imagine what the wind can do in piling up dust. During our dry summer large quantities of dust are carried away by wind. We can watch the progress of the sandhills on the coast at our watering places. We see fences almost covered by sand, and houses being overwhelmed in the same manner. Vegetation plays an important part in preventing the surface soil from being blown away. Our greatest dust storms occur on wide, treeless plains. In hot climates the most important agent engaged in breaking down rocks to dust is the change in temperature. In cold countries the great weathering agent is frost—intense cold. We know that water whilst changing into ice expands with almost irresistible force. If a bottle be filled with water, corked tightly, and exposed on a very cold night when the temperature falls below zero, it will be found to be cracked when examined next morning. On the Continent of Europe and North America it is no uncommon occurrence for water pipes to burst during cold weather. Almost all rocks, and especially sandy ones, are somewhat porous. They therefore absorb water. During exceedingly cold weather this water

freezes, expands, and forces particles of rock apart. When the ice melts the rock particles easily separate. Consider a lump of hard soil. Rain falls. The clod becomes saturated with water, which freezes, expands, and forces the particles apart. The clod remains as hard as a stone until the thawing sets in, when it falls to the finest powder—in a finer state of subdivision than can be obtained by any crushing machine in existence. Frost in these countries is a great tillage implement, and is a farmer's friend. When frost damages our crops we are apt to regard it as a curse rather than a blessing. It may do harm at times, but it also does incalculable good. Have you ever ascended the side of a hill in a cold climate and noticed the number of loose stones that make walking a great effort? These stones are the result of the work of frost. They have been broken from the rock composing the mountain, and are gradually working their way down the side of the hill. In Scotland such accumulations of loose stones are termed 'scree.' In humid countries the face of polished granite rapidly deteriorates. Cleopatra's Needle retained its polished face for centuries on the banks of the Nile, but on removal to London it was soon found necessary to apply a waterproof varnish to protect the surface. In Canada and the United States, and many other countries, the same precautions have to be taken to protect polished slabs. When flagstones have to be quarried it is customary for the workmen to saturate the surface of the rock with water before winter sets in, for the rock is found to split more readily along the bedding planes under the action of frost than by any other means."

(To be continued.)

Utera Plains, August 24.

(Average annual rainfall, 14in.)

PRESENT.—Messrs. P. Sinclair (chair), A. Venning, A. Ramsey, W. Gale, W. Stephens, J. and M. Abrook, H. T. and T. C. Hornhardt, A. Barker, M. Hunt, H. Hill, H. D. Rule, G. C. Bilney, F. Braunack, R. Hill (Hon. Sec.), and three visitors.

COMMERCIAL FERTILISERS.—The following paper was read by Mr. Ramsey:—"Artificial manures are used for the express purpose of obtaining an increased yield, and thereby a greater profit. Whether the fertiliser used will yield a profit depends chiefly upon the manurial requirements of the soil and the particular crop. If the manure happens to suit the soil, climate, and conditions generally, an increased yield must result. At present the majority of farmers use phosphate because their neighbors obtained a good yield by so doing. Farmers, as a rule, know very little about their soils and the requirements of their crops. South Australian farmers are no worse than others in this respect. They use manures more profitably than farmers in the eastern States. In some parts of New South Wales they are afraid to use superphosphate. Not until several good crops have been grown in the district with super. can they be induced to use it. It is certainly a good plan for farmers to conduct experiments on a small scale on their own farms; by so doing they learn much in regard to the climatic conditions prevailing. There are several different systems of manuring in vogue in many parts of the world. No system is absolutely the best; each has its own particular merits. Ville's method assumes that plants may, as far as manures are concerned, be divided into three groups. One group is specially benefited by the application of phosphates, a second by potash manures, and the third require nitrogen in abundance. Ville's plan suggests that the dominant fertiliser should be applied in excess to the particular group. By this system wheat, rye, oats, and barley require nitrogen in excess; phosphoric acid is required for turnips, maize, sorghum, sugarcane; while peas, beans, clover, and potatoes require potash manures. This plan does not bar the use of other manures to the group of plants mentioned. It implies that, while phosphatic and potash manures may be needed by wheat, oats, and barley, nitrogen must be the plant food applied in excess. When the soil is fairly well supplied with plant food and the field is well tilled this system of manuring should give good results. Wagner's system was propounded by the German scientist of that name. According to Wagner, as phosphatic and potash compounds and most mineral constituents of soil are not likely to be leached out, whereas nitrogenous compounds are so soluble that they are easily lost in the drainage waters, it follows that nitrogenous fertilisers must be carefully used. The mineral elements are cheap, the nitrogen compounds dear. The economical use of nitrogen will mainly depend upon the abundance of phosphoric acid and potash present. When phosphoric and potash manures are applied in excess, the nitrogen must be applied when the plants are best able to make use of it; that is,

during the growing period. It is also better to use small amounts of nitrogenous manures at such times and quantities as the conditions demand. As the name implies, the analysis system is based on the analyses of plants, which tell us their food requirements. We can, from an analysis, calculate the amount of plant food per acre removed by certain crops. Different formulas must therefore be recommended for each crop, and the phosphoric acid, potash, and nitrogen are used in the proportions in which they exist in the plants. This system, although it may result in large yields, is an expensive one. A soil may be rich in phosphoric and potash, and may not need the addition of either of these plant foods to secure good results. A manure may be used without any knowledge of the conditions of soil and the crop requirements. If a good yield results, all is well; but a poor yield at once shakes the farmer's belief in fertilisers. As before mentioned, almost every farmer in this State uses a phosphatic manure. Now we know that all soils are not alike, either in chemical composition or physical condition. A sandy soil requires different treatment from that given a stiff clay. Yet the farmers apply super. to both, and oftentimes with good results. A farmer leaving the north for the southern districts expects his farm practices in the former to suit the conditions prevailing in the latter. Such a change is not so violent as one, say, from England to Australia. The Englishman has looked upon fallowing as a wasteful practice; he has also been taught to use nitrates in excess on his wheat crop. Let him try such system of manuring in South Australia and in every instance he will come out on the wrong side of the ledger. For a system to be successful the principles governing such system must be sound. Different soils contain varying amounts of plant foods. A certain soil may be lacking phosphates, but may contain sufficient potash and nitrogen to produce a maximum yield. In such cases phosphatic manures only are needed, and it would be wasting money to apply others. It seldom happens that all three plant foods are lacking at one time. A chemical analysis of a soil may indicate that all the plant foods needed by a crop are present, and in more than sufficient amounts to produce big yields for many years. Still, the conditions may be such that only poor yields are obtained. In such cases the only sensible way of finding out the proper fertilising ingredient required is to put the question to the soil. A few simple experiments could be conducted on the farm. A certain number of plots could be set aside and different fertilisers used on each separate plot: phosphates in one, potash manures in another, and nitrogenous compounds in a third. Then a combination of the three elements should be used on one plot. A check is also necessary. To be worth anything such experiments should be carried out for a number of years on the same plots. The experimental plots should receive exactly the same treatment as the rest of the field. Generally the eye will detect any difference of growth; nevertheless, it is necessary that each plot should be separately harvested and the results tabulated; and just here let it be stated that this operation must be carefully conducted. The weight of grain and straw from each plot should be carefully calculated. The result of one year's experiment must not be considered conclusive, but the average for several years will give much valuable data to work upon. No matter how many tests are carried out by the 'plot' system there are no more truthful results than those of experiments conducted on field plots. The plot system is no doubt of great scientific interest. With such experiments the conductor has almost complete control of every factor. Not so the farmer. He has little control over the field. True, he can plough and sow and reap, but further than that he is powerless. There are so many conditions to be considered on a large scale that do not present themselves in the plot system. The experimenter has complete control of drainage, physical conditions of the soil, immunity to insect or fungus pests, and the amount of plant food present in the soil. The farmer has little, if any, control of these factors when experimenting on a big farm. Farmers should not consider the use of artificial manures a panacea for all the ills to which a plant is heir. No matter how much manure is applied, the result will be poor unless the farmer works his soil intelligently, sows the most suitable wheat for his district, and destroys fungus pests attacking his plants. The constant use of artificial manures necessitates most careful farming. It means that a proper amount of humus must be kept in the soil. Where it is impossible to apply stable manure a green crop must be ploughed in the soil. As artificial manures actually supply plant foods, it follows that when such manures have been sensibly employed a soil must become richer year by year. We, in South Australia, wish to obtain maximum yields by the use of super. A time must come when our soils will be depleted of potash; we will then find it absolutely necessary to apply both potash and phosphatic manures. We use such small amounts of phosphoric acid that one is inclined to doubt whether the increased yields are due to the use of this plant food. We are certain that the farmers to-day are getting much better yields; not because they are using phosphates, but because of the more intelligent method of farming now adopted. More attention is being paid to all forms of tillage

operations, wheats are more carefully selected, and farm implements are greatly improving. All these factors tend to increased yields. We have still much to learn about farming. The Government cannot be accused of spending too much money on experimental farming." In discussing the paper, Mr. A. Venning said the farmer should dress his crops with different manures, with the idea of ascertaining which returned the greater profit. Mr. J. Abrook considered the increased return from the application of super. was proportionately greater in the case of the poorer lands than the richer. The Hon. Secretary had used fairly heavy dressings of super. with good results. Every farmer should each year experiment on his holding. Different plots should be harvested separately and carefully. It was essential also to see that any increased yield obtained was correctly attributed to the factor which had brought it about.

DRIFTING SAND.—Members were of the opinion that it was not advisable to fallow to any depth country that was liable to drift. The rubbish should be left near the surface, and this would assist in preventing the movement.

Yabmana, June 29.

PRESENT.—Messrs. J. N. McCallum (chair), N., R., and A. McCallum, J. F., J. Y., and A. Robertson, W. W. Lindsay, T. G. Strother, C. Bartel, F. Schirmer, G. W. Sharp, J. Penna, and M. K. Frost (Hon. Sec.).

FARM HORSES.—Mr. J. Penna read the following paper on this subject:—"In this district there is room for great improvement in our horse stock. The draught horse is the best to breed on the farm. I advocate the Clydesdale, as it is active, with plenty of grit and fire and abundance of bone and muscle, which is necessary for heavy carting. The selection of the sire plays an important part. Study its pedigree, and see that for generations it has been kept true to type. When characteristics have been transmitted from generation to generation they become fixed, and the good points of pure-bred sires are more likely to be transmitted to their progeny than are those of half-breeds. Size, style, conformation, and quality are points to be studied. Farmers who do not possess a stallion should patronise the best available, even if it costs a few extra pounds in service; it is money well spent. A good horse always commands a good price, while the market is glutted with weeds. A large amount of money has gone from South Australia to Victoria and New Zealand for horses, and some fine specimens have been procured; but there is still a tendency to utilise the cheap horse. This is to be regretted. Australia has the finest climate in the world for horse-breeding. Our open pastures are unequalled, but the high prices ruling during the last few years have made people careless. If we wish to hold a place in the world's market, we must keep some of our best from which to breed, and not the culls that export buyers have refused. If we go on with a downward tendency, our reputation will be lost. After breeding, feeding is the most important factor. One well-fed horse will do as much work as two under-fed animals. A foal should be well cared for from the time it is weaned. If the pasture is short a little feeding will pay. It costs less to feed a horse in good condition than a horse in poor condition. I would break colts to light work at the age of two and a half years, taking care to avoid scalding the shoulders. Too much corn often causes trouble. Working in wet weather is also a bad practice. Where it is possible, horses should be provided with a warm stable. To stand in the wind and rain all night after a hard day's work would tax the constitution of any animal. We are mainly dependent on our horses for a livelihood, and therefore they are worthy of consideration." In the discussion which followed members generally agreed with the paper, but some thought the Clydesdale was too heavy for ordinary farm work.

Yadnarie, August 23.

(Average annual rainfall, 14·07in.)

PRESENT.—Messrs. W. L. Brown (chair), J. A. Kruger, F. W. and A. A. Jericho, A. Spriggs, R. H. Parbes, F. H. Stubings, R. B. Deer, L. H. Marston, C. H. Mowat, G. B. Kobelt, H. Pearce, B. B. Crosby, J. J. Deer (Hon. Sec.), and three visitors.

INCREASING THE WHEAT YIELD.—Mr. W. L. Brown read the following paper on this subject:—"In South Australia the average yield is low when compared with that of England or New Zealand. Occasionally there is a grower who obtains 40bush. per

acre, but this is an exception. The usual thing is an 8bush., 12bush., or 15bush. average. The agriculturist in this country has difficulties to encounter. Drought, disease, and poor markets have given the wheat pioneer setbacks. The appreciation by the average farmer of improved methods is necessary to increase the yielding capacity of the land already occupied and under cultivation. Every farmer does not recognise the value of artificial fertilisers, or make following a general rule, or put into practice an intelligent system of crop rotation, or obtain the best seed of the variety best adapted to his soil. To ensure the value of an experiment, a careful account should be kept of the labor and cost, so that it may be seen, when the plot is harvested, what the result is financially. One acre yielding 20bush. is more than twice the value of two acres yielding 10bush. each, because the labor is decreased by half. It is this that induces the grower to prefer the careful cultivation of 100 acres to the careless cultivation of 200 acres." In the discussion which followed, members thought that more phosphates could be used to advantage in this district, and that the methods of cultivation could be improved.

EASTERN DISTRICT.

(EAST OF MOUNT LOFTY RANGES.)

Coonalpyn, July 27.

(Average annual rainfall, 17½in.)

PRESENT.—Messrs. Wall (chair), Gurner, G. E. and R. F. Venning, Bone, Hill (Hon. Sec.), and one visitor.

FIREWOOD.—In a short paper on this subject Mr. T. H. Wall expressed the opinion that the price of wood to the consumer was too high in proportion to the rate paid to the man on the land for it. Although some months ago the rail freights were reduced, there was apparently no direct benefit to the retail purchasers or the farmers. The wholesale wood merchants were offering 8s. 6d. per ton on trucks, Coonalpyn, for roots at the present time. The rail freight per ton to the city was 6s. 11d., which brought the price of the roots to 15s. 5d. on trucks, Adelaide, whilst the consumer was asked to pay from 28s to 30s. per ton.

Forster, August 3.

(Average annual rainfall 10½in.)

PRESENT.—Messrs. C. Hayman (chair), J. Searle, J., F., and W. Johns, J. G. and R. Whitfield, W., T., and H. Searle, E. Towill, C. P. Payne, W. J. Sears (Hon. Sec.), and one visitor.

THE AGRICULTURAL BUREAU.—Mr. J. G. Whitfield read the following paper on this subject :—" We often hear the question, ' What is gained by attending Bureau meetings ? ' In my opinion a great deal is gained, especially by the young men. If all members attended regularly, brought their friends with them, and took more interest in the meetings, they would soon find that a great amount of good was being done throughout the State. They would get practical hints on all branches of agriculture from State agricultural advisers, professors, veterinary surgeons, and practical farmers, whose views should greatly help all classes of men if they are anxious to learn. The value of this interchange of ideas, experience, and observation to each individual member of the Bureau and to the State as a whole, cannot be overestimated. I would advise our young men (I am glad to know we have several in our Branch) to take a deeper interest in all matters that come before the meetings. They may not just now appreciate the benefits, but in later years they will wish they had given them more thought. Some will no doubt continue farming. Consider now the advantages you have in the practical advice you get through your *Journal*. I say your *Journal*, because you not only have reports of your own meetings published, but of all the meetings held throughout the State, and this should enable you to gain a greater knowledge. In years to come it will be a great help, not only to yourself, but also to those with whom you are associated."

Geranium, July 27.

PRESENT.—Messrs. R. L. Jacobs (chair), Lang, Reed, W. J. Mitchell, Wendelbourne Hammond, Dohnt, and W. Pannell (Hon. Sec.).

HORSES.—An interesting address on the subject of common ailments of the horse was delivered by Mr. R. L. Jacobs, in which he stated that to the experienced horseman the general appearance of a horse immediately betrayed the state of its health. When an animal was in good health it stood erect and squarely on all four feet, and there was an easy rythmical movement, and an apparent even distribution of the weight of the body over the feet. The appetite was good, and when in the paddock the animal would be continuously grazing. The coat should present a sleek appearance, the ears being alert and evenly pricked up, and the eyes bright and glistening, without being excessively moist. The normal temperature of a horse was 100° to 101°, the pulse 36 to 40, and respiration between 12 and 16 to the minute. Without knowledge of the normal conditions, it was not possible to accurately diagnose in the case of sickness. Horse-owners should not be in too great a hurry to dose the cases. The history of the trouble should be carefully studied. The causes of various complaints, together with the simplest means of curing same were dealt with, and stress was laid on the necessity of prevention.

Hooper, August 14.

PRESENT.—Messrs. J. R. Beck (chair), A. Macdonald, G. G. Pitt, C. S. Hall, E. G. Colton, W. N. Pearce, W. J. Pearce, E. O. Brown, A. W. Lawrie, C. B. R. Wright (Hon. Sec.), and two visitors.

MIXED FARMING.—The following paper was read by Mr. C. S. Hall:—"It is a serious mistake for a farmer to confine his energies to the growing of cereal crops alone. Some scheme of mixed farming should be adopted. In starting in new country, I would advise the following scheme:—When the farmer has his crop in, he should plant ornamental trees about his homestead, and clear and grub an acre or two for fruit trees, lucerne, and vegetables. He should select a spot as well protected from the wind as possible, and one that can be irrigated. The fruit trees should be planted on a slight slope. A fair amount of attention is necessary for the welfare of the trees for the first few years, but, when they are well established very little time need be given them. Lucerne should be planted in a good depth of soil, free from stumps. The ground should be well stirred up before the seed is planted, the best time for which is August. A good dressing of farmyard manure should be applied, and bonedust should be drilled in when sowing. The land should be well drained, for if water is allowed to remain on it the result will be detrimental to the growth of the lucerne. Most vegetables can be grown here, especially tomatoes and melons. These need little attention, but pay well. No farmer should be without a few head of poultry. Pure-bred birds pay best. If the birds are coarse about the head they will generally be poor layers. They should be fairly broad at the back, compact, low set, bright, and active. They will do much better and lay better if shut up. The yards should be well protected from the wind, with natural shade provided. They should face the east, and a warm house should be in each yard. Testing of hens is a practice which should be adopted. Keep the rooster away from them, except at breeding-time, for they do better, and the infertile eggs keep better. Feed a pollard mash in the morning, greens at mid-day, and grain at night, and give fresh clean water regularly; also provide plenty of grit and litter. Pigs are profitable. A good strong wire-netting yard and warm sties should be erected. Cracked grain, well soaked, makes suitable feed. If the grain is given dry, it should be crushed. The pigs do well on piemelons. This country is not suitable for breeding on a large scale, but every farmer should have one or two pigs. Sheep, of course, are a very profitable source of income, and every farm, once established, should have a small flock of them. Mallee roots are an asset to those farmers who are within a reasonable distance of the railway, and it is a great mistake for those so placed to burn the roots."

Monarto South, August 23.

PRESENT.—Messrs. G. Patterson, (chair) A. Patterson, R. E. Andors, A. P. Braendler, J. and H. Frahn, G. Gogal, J., E., and R. Hartmann, A. Harper, H. Hein, E. Kuchel J. G. H. and G. H. Paech, A. Schenscher, C. Thiele, G. Thomas, J. Daly, C. F. Altmann (Hon. Sec.), and six visitors.

PREAMIMMA WELL.—In a short paper the Chairman dealt with the proposal to connect the Preamimma Well by a pipe with the main road, a distance of about one and three-quarter miles. He contended that if this were carried out a great deal of trouble and expense would be saved those who had to cart water, and he supplied the following estimate of the cost of the work :—9,240ft. of 1½in. galvanized piping, £217 2s. 9d. ; two 3,000gall. tanks, £21 10s. ; windmill, £25 ; railage, £5 ; carting, erecting, and laying pipes, £6 ; ball taps, stands for tanks, sundries, £6 ; a total of £280 12s. 9d. If 1½in. piping were used the cost would be reduced to £226 12s. 9d. Members generally agreed that the estimate supplied was somewhat low.

Morgan, August 24.

(Average annual rainfall, 9in.)

PRESENT.—Messrs. R. Wohling (chair), E. Hausler, O. Hausler, R. Wohling, jun., E. French, J. Heppner, J. Pope, and H. Wohling (Hon. Sec.)

HORSE FEED.—Mr. R. Wohling, jun., read a paper, in which he stated that the farmer in the Morgan district would be well advised to set aside about 40 acres of good land for the purpose of growing hay. Loose and sandy soil was better than clay, as the crop would not grow in the latter during the cold weather. However, this could to a large extent be remedied by the use of super. Feed for five horses for 12 months had cost £82 15s., and he was of the opinion that if he had grown the feed himself the expense would not have been so heavy. Mr. French, in discussing the paper, recommended the keeping of cocky chaff and straw for use in bad seasons.

Parrakie, August 24.

PRESENT.—Messrs. F. J. Dayman (chair), A. J. Beelitz, H. Deiner, C. Heinzel, O. Heinzel, W. Threadgold, F. W. Randall, F. W. Gravestocks, A. F. Dayman, J. Temby, C. E. Hammond, R. L. Beddome, J.P., R. E. Jose, F. S. Dayman, M. Kildea, N. Good, T. Lewis, M. Cooney, T. Willis, J. Oharo, A. Heinzel, S. R. Good, A. S. Johncock, A. C. Hameisten (Hon. Sec.), and seven visitors.

FRUIT AND VEGETABLES.—Mr. A. J. Beelitz read the following paper :—It would pay every farmer to put in about 50 fruit trees and about 200 vines on a piece of soil cleared and well ploughed with a share plough. The fruits should be planted about 20ft. apart each way. As the district is inclined to be very frosty, I prefer them at the foot of a sandhill on the south side. Vines should be brought well up from the ground, and planted about 10ft. apart each way. The farmer should also put in about one acre of water melons, and one or two acres of pie melons, pumpkins, &c., which grow remarkably well and make good feed for cows, pigs, and poultry, and are suitable also for household use. These should be planted at the end of September or beginning of October, in rows about 6ft. apart, on a piece of fallow land, protected from north winds and drift sand. A plot of cucumbers and tomatoes, grown on land well dressed with stable manure during the winter, dug down, and another dressing applied before planting, would mean a big saving in the greengrocer's bill."

Pinnaroo, August 17.

PRESENT.—Messrs. B. L. Harfield (chair), A. U. Burman, F. G. Bonnin, J. Docking, H. E. Dibben, F. H., P. J., and R. Edwards, L. M. Ferguson, F. Hunt, H. C. Hill, W. H. and M. Kelly, H. Ledger, C. Lee, J. Lotheby, F. Laycock, M. McCabe, E. H. Parsons, A. I. Reed, C. A. E. Schiller, J. Scales, W. Venning, L. H. Wright, W. Wilson (Hon. Sec.), and four visitors.

STRIPPERS AND HARVESTERS.—Two members contributed papers on this subject. Mr. R. Edwards said—"I consider the stripper more suitable than the harvester for anyone farming on anything like a large scale in this district, but where a farmer is doing his own work it is probable that the harvester is more suitable ; at least one man in this district last year took off over 250 acres single-handed with one harvester. This could not be accomplished with the stripper, as this necessitates at least two men at the winnower ; but where a large area is to be dealt with I favor the strippers and a power winnower. The winnower can stand in a convenient place instead of being hauled about all over the paddock, as is the case with the harvester. This is a big consideration in a

light, sandy soil such as we have here, which makes it necessary to save every pound of haulage possible. There is more waste with the harvester. The stripper can only waste off the comb, but the harvester has the comb waste and that of the riddles, and on some machines there is leakage from a number of other places as well. It is impossible to avoid some waste off the riddles where there are stumps in the ground, as the pace cannot be kept even. When the main wheel comes down off a stump it must quicken the speed of all the machinery, and wheat is often thrown off the sieves in consequence. It is also said that the harvester distributes a lot of rubbish over the ground, as when a sufficient blast of wind to properly clean wheat is being maintained in the winnower it is quite strong enough to blow small seed, wild oats, &c., over the tail. Perhaps the most important argument in favor of the stripper is the saving of the cocky chaff, which in a season such as we have just passed through is a valuable fodder. A fair supply should always be kept on hand in case of a poor season. Chaffsavers can be attached to harvesters, but as far as I can learn they are anything but satisfactory and entail a considerable loss of time. The harvester advocate will say it is a big advantage to have the wheat cleaned as it is taken off, which fact I freely admit; but the best method is to strip the crop, have the winnower in the paddock, and clean the wheat as it comes in. A cloth should be placed at the elevator of the winnower and the strippers emptied on to this. Do not heap the wheat and clean it afterwards. There is too much waste caused by the sandy floors and rain. By adopting the above method the cocky chaff is carried from the machine and placed in large heaps convenient for covering with straw, to be kept dry for the stock when necessary. If a chaffsaver is used on a harvester, which is rarely the case, the chaff is deposited in small heaps, and a considerable amount of time has to be spent in carting or throwing it into a large stack. Then there is the question of labor. The harvesters can be worked with less labor than the stripper, but it is more expensive and harder to get. It is difficult enough to obtain a man competent to drive a stripper, but it is infinitely more difficult to obtain one who can be thoroughly trusted with a harvester, and a higher wage is usually demanded. The labor saved will not amount to much, after allowance has been made for the extra wages, horses, horsefeed, and extra tackling necessary to work three or four harvesters." Mr. C. Lee stated that with the increased size in the areas cropped, improvements in the harvesting machinery were necessary. The scythe and sickle were followed by the stripper and winnower, and then the motor winnower. Continuing, the paper said, "The troubles that confront the farmer to-day are those of wages and the difficulty of securing competent workmen. The harvester fairly meets these difficulties, as can be shown. One man with four good horses can reap, clean, and bag in a fair average crop, say, about 50 bags a day. Allowing £2 10s. per week for his wage, the crop could be taken off at the comparatively low cost of 2d. per bag. It will only cost him 4d. per bag to reap, clean, and place same ready for market. The cost of feed and chaff would be the same with the harvester as with the stripper. The average price for cleaning by motor would not be less than 3d. per bag. The cost of harvesting with the stripper and winnower can be set at 5d. per bag. The difference would amount to a fair cheque on some of the farms in Pinnaroo in a good season. The fault attributed to the harvester is a waste of chaff, but a chaff carrier can be very cheaply made and fixed on the machine. I have worked harvesters for two seasons and have had no trouble with chaff getting into the bags when the machine is stopped and started in the crops, or in turning corners. There is not so much chaff in the wheat as is the case with the hand or motor winnower. Harvesters, if properly looked after and kept oiled by the man in charge, are little, if any, more trouble than strippers. In the former there are two machines working in one, and there is bound to be wear and tear. The saving to the farmer more than pays for extra parts. There is less waste with the harvester than with the stripper, even when dealing with a low crop. The harvester will take much better than the stripper a crop that has gone down by wind and rain." A lengthy discussion followed. Mr. McCabe favored the harvester, as the farmer could start operations two hours earlier than when using the stripper. The harvester was often said to be the means of "fouling" the land, but he had seen properties equally as dirty before the introduction of the harvester. Mr. Venning said that when the cleaning was done by power winnower there was nothing to prevent a stripper starting as early in the day as a harvester. Mr. Docking did not think sufficient improvements had been made in the harvester to justify its place on a farm. If the grain were put in a heap before cleaning a stripper could commence operations at least 10 days before the harvester without any harmful results. Mr. Schiller conceded that the harvester was a labor-saving machine, but emphasized the fact that its handling required a thoroughly competent man. While the average farm hand could work a stripper, it was not so with the harvester, and experienced hands were not always easily secured. He

avored the stripper. There was not much waste grain when it was put into heaps if it were cleaned up early and care were exercised when bringing the stripper in for the purpose of emptying. The saving of "cocky" chaff alone was an important factor, as when mixed with crushed corn this by-product was of immense value for stock feed. Mr. W. H. Kelly had been farming for 50 odd years, and had never found reason to condemn the stripper. An important point in connection with these machines was their simplicity. The only wheat lost was that from the comb. The harvester not only distributed it in this way but also blew and shook it out. He believed the stripper had come to stay, but the harvester would soon be laid aside. Mr. P. J. Edwards had always used the stripper and motor winnower, but was of opinion that a great deal was to be said in favor of the harvester. The saving of labor was a very important item to the farmer of to-day. By the use of the harvester a crop could be gathered and cleaned by just so many men as would be necessary for the driving of the machine. It took three men to work a motor winnower when fed by four strippers in a good crop, and a less number of strippers would not keep a winnower fully supplied. The motor was not sufficiently simple for the average farmer to understand and manage. Some members had had trouble in respect to their motors, and were greatly inconvenienced thereby. Other points to be taken into consideration were that the motor required benzine and a liberal supply of oil. Mr. Ledger was accustomed to the use of stripper and power winnower, but recently had been seriously contemplating a change. He attached little importance to the loss of seed; the saving of cocky chaff was perhaps the most vital point. Strippers were not desirable on small farms. Mr. Parsons questioned whether it would not be possible for two farmers in a small way to share the machinery, and so harvest by this means. Members thought such a scheme as this was hardly practicable.

Renmark, July 23.

(Average annual rainfall, 11in.)

PRESENT.—Messrs. H. DeWitt (chair), J. S. Huggins, H. S. Taylor, H. D. Howie, R. Nuthall, C. J. Everard, M. B. Genest, L. L. McDougall, F. Basey, F. Cole (Hon. Sec.), and one visitor.

PRUNING DECIDUOUS TREES.—It was stated that Mr. Laffmann, late of the Victorian Department of Agriculture, believed that the leaders of fruit trees should not be shortened back, as a cut back leader invariably forced strong growth. By removing the shoots altogether, better results with the fruit spurs on the lower limbs of the tree would be obtained. Mr. Howie had had satisfactory results from apricot trees treated in this way. Mr. Everard had seen some trees in Adelaide on which strong growing leaders were tied down instead of being shortened back. The results were said to have been very good.

SOUTH AND HILLS DISTRICT.

Cherry Gardens, July 23.

(Average annual rainfall, 35·3in.)

PRESENT.—Messrs. S. Chapman (chair), C. Ricks, C. Lewis, A. Broadbent, A. Jacobs, J. Tozer, H. Jacobs, A. R. Stone, E. Broadbent, H. Lewis, T. Jacobs, jun., J. Lewis, T. Jacobs, G. Hicks, J. Mildwater, S. H. Curnow (Hon. Sec.), and one visitor.

EXHIBITS.—Mr. Ricks tabled some samples of Berseem clover which had grown, with the aid of irrigation, to a height of 8in. He did not think the clover, as an early feed, gave any better results than barley. He intended, however, making a sowing in December, and irrigating by means of sprinklers.

BUSH FIRES ACT.—Mr. T. Jacobs initiated a discussion on this subject. He considered that it was absolutely necessary that the Act should be amended. It was very suitable for the North, but it did not meet the requirements of the Hills districts. He read extracts

from the 1885 Bush Fires Act, clause 4 of which said that no fire should be lighted for scrub-burning during the months of November, December, or January, on pain of a penalty of £50. It was an exceptional year when a scrub fire would run in the grass and do damage during December. If the scrub could have been burnt in October and November, when it was quite safe, the disastrous fires of last summer would not have occurred. Residents in the Hills districts should be allowed to burn in the night time, as the fires then burnt more steadily, and were consequently under better control. Mr. Ricks agreed, and suggested that the Act should be amended to allow of landholders in the hills burning scrub during November, February, March, and April, during night or day. Mr. Jacobs said that much of the hills scrub went for years without being burnt, simply because it would not burn satisfactorily at the time allowed in the Act. During the many years he had lived in Cherry Gardens he only remembered one grass fire. Other members spoke in favor of an alteration in the Act. Members then discussed the possibilities of organisation for the purpose of controlling bush fires. Messrs. Stone and Mildwater agreed that good work could be done in this way. It was suggested that several of the best bushmen in the locality should be accepted as leaders, and the whole of the fire-boaters should act under their directions. It was felt that much valuable property could be saved in this way.

Hartley, July 27.

(Average annual rainfall, 16in.)

PRESENT.—Messrs. B. Wundersitz (chair), J. F. Tydeman, J. M. Hudd, W. Bermingham, W. Brook, S. Pratt, W. Richardson, G. Hill, H. G. Phillips, J. Stanton (Hon. Sec.), and one visitor.

QUESTION BOX.—A number of questions were dealt with by members. It was thought that slides were better than wheels for fixings for harrow swings; and members unanimously agreed that more satisfaction was gained from chaff when fed to horses than was the case if the hay were fed long. The majority of those present considered it did not pay to insure mares about to foal, and for the treatment of sore shoulders in horses it was thought advisable to keep the shoulders clean and place a bran bag under the collars when the horses were working.

FARM LABORERS' BLOCKS.—Mr. J. M. Hudd, at the June meeting of the Branch, read a paper in which he set out his reasons why the proposal to survey small blocks of land to provide holdings for farm laborers was impracticable.

Lyndoch, August 22.

(Average annual rainfall, 23in.)

PRESENT.—Messrs. A. Springbett (chair), A. Klaube, E. J. R. Woolcock, H. Springbett, J. Linke, H. Kennedy, P. N. Burge, W. F. Haese, J. Mitchell, G. W. Warren, E. Filsell, and J. S. Hammatt (Hon. Sec.).

SAND IN HORSES.—Mr. H. Springbett remarked that he had successfully treated horses suffering from the effects of sand as follows:—A drench consisting of one handfull each of coffee and sugar and three-quarters of a pint of water brought to a boil was put into a one and a half pint bottle, which was then filled with new milk, was given. For the next two days the animals were fed with chaff and pollard.

Meningie, July 27.

(Average annual rainfall, 19in.)

PRESENT.—Messrs. Mincham (chair), Hiscock, Ayres, A. and F. P. Dainty, A. and E. Pettit, Hill, Court, Williams, I. and I. R. Coad, Yates, Tregilgas (Hon. Sec.), and seven visitors.

WINDBREAKS.—In a short paper on this subject Mr. A. Dainty drew attention to the necessity of growing hedges in this district. Whilst the boxthorn, the briar, and the urze were suitable for this purpose, the difficulty was that these plants spread so rapidly that they soon got out of control, and there was every indication that the first named would be a great curse to landowners in the district within a few years.

Mount Barker, July 25.

(Average annual rainfall, 30·96in.)

PRESENT.—Messrs. J. Brinkley, H. and F. Treleaven, A. Ferguson, C. Crompton, F. H. Follett, F. von Doussa, F. Simper, Jas. Cleggett, J. Morris, H. and B. Pope, G. Milne, R. H. Grimes, J. Thomas, J. Smith, H. N. Bell, A. P. Herbertson, L. Cornish, B. Stephenson, J. Fidler, S. J. Bishop, D. L. G. Monfries (Hon. Sec.).

THE SILO.—Mr. D. L. G. Monfries read the following paper :—" In introducing my paper on 'Silos and their Advantages,' I wish to state that some of my remarks may seem contrary to the theory that some of you, no doubt, have gleaned from articles published on this important subject ; but my paper is going to be a practical one, and not a theoretical one. There are three kinds of silos—stack, overground tub, and pit silos. As I am not very well acquainted with the tub silo, which is used extensively in Canada, I will have nothing to say on this particular style. The stack is favored by some mainly. I think, because it does not cost the farmer as much to put his silage down ; but I feel quite confident that the silo for us is the pit silo, as there is nothing like the heavy handling, nor the waste round the edges of the stack. The pit silo, if possible, should be constructed in the side of a hill. This does away with heavy pitching of green stuff, and there is no trouble in getting it out when ready for feeding purposes. I favor a pit of about 13ft. square and 15ft. deep, which will hold enough ensilage to feed 20 cows for about four months, that is allowing each cow one cubic foot per day, or in weight 40lbs. to 45lbs. This, of course, assumes that the cows are allowed to graze as well. Build the silo of brick, cemented over, with the corners rounded off, to enable the fodder to be well tramped, which is a most important factor in making good ensilage. In the case of right-angle corners, tramping is most difficult, and this is usually where, together with the sides, the most waste occurs. Have a door-frame built in the lower side, where slabs can be fitted, one above the other, till the frame is completely filled in. When this is done it is advisable to paste sheets of unbleached calico on the slabs to prevent air getting between them and thereby spoiling any silage. A sliding roof is also a good idea, as it can readily be moved during filling and pushed back afterwards. A great advantage of silos is that during years of plenty, fodder that otherwise would have wasted may be saved for droughty periods, as ensilage will keep for years. Silos in America are termed (and rightly so) the farmers' 'save all.' Our own silo is of the size mentioned earlier, and is only 3ft. above the ground at the top (the filling side), and 4ft. 6in. in the ground at the lower side ; consequently it reduces the handling to a minimum. Any green stuff will make ensilage, but the better the fodder put in the better will be the outturn. True enough, stock will eat ravenously variegated thistles, artichokes, and any other weeds when made into ensilage, but whether they do as well on it as on other good fodders is quite another thing. Maize and Indian corn, sorghum, and horse beans are used with great success, but the best crop is reaped from a sowing of 2bush. of oats, 8lbs. of vetches, and 20lbs. of peas to the acre. Lucerne and clover make capital ensilage. Our winter is very cold, and where we can keep 40 cows in the spring and early summer, we cannot keep 10 during the winter unless we make provision for them. By conserving fodders and native grasses, which would otherwise lose all their nutritious values and be of no use whatever, we can keep our cattle in good healthy condition. Crops for ensilage should be cut before they get too ripe, and in the case of oats, peas, and vetches, I favor cutting just as the oat head comes out. By that time the peas are nicely in pod, and the vetches about the height of the oats. The stems of the oats are not hollow, and therefore there is an absence of air, and the fodder is not so liable to go musty round the edges of the pit as is the case when cut riper. Lucerne should be cut when it is just coming into flower, and it then makes ensilage of exceptional quality. When filling the pit there is absolutely no necessity to work at express speed, as filling steadily is just as good, and the ensilage, when taken out, is of quite as much value. A great advantage ensilage has over hay-making is that one can go on filling the silo irrespective of wet weather, as this does not in any way hurt the silage. In the case of hay it would simply spoil the crop. An average crop of green stuff yields from 6 to 9 tons per acre, and the same crop cut for hay would yield from 30cwt. to 2 tons. With the exceptional feeding qualities that ensilage possesses, especially in the production of milk, everything is in favor of the latter. The cattle are more fond of it than they are of hay. Care must be taken in filling the pit to keep the corners and edges well tramped, otherwise the air will get in and spoil a great part of the food. The middle, of course, is not so liable to spoil, but the whole surface must be looked to in this regard. Most persons believe in chaffing the fodder, but where a farmer intends feeding in the fields it should be put in long, as it is not so liable to waste, and cattle will eat up every scrap. Do not let the temperature of the silage get below 80°, or over 115 degrees Fahr. A simple, yet effective way of finding out if silage is about the right

temperature is to push a sharp piece of iron down into it, and leave it there for some time. If, when drawing it out, it is too hot to hold, there is too much heat in the silo. If, on the other hand, the iron is only just warm, it is too cold. To get the silage cooler tramp it well, or add weight. To get it warmer let it stay for a day or so and do not cart on to it. A load of any old weeds, with a load of earth thrown on top of them, and weighted with timber, is an excellent means of covering the pit. By doing this, if any is spoilt, it is never more than the layer of weeds. Roughly the cost of carting, cutting, and filling is about 1s. 6d. per ton. Ensilage can be fed at any time after six weeks from being filled, or it can be left as long as desired. During summer it is a preventive against dry bible, and I have seen times when people were losing their cattle all round, while those feeding on ensilage did not have one case among their herd. I believe dry bible is caused through nothing else than feeding with all dry and no green or succulent matter, and I advise all farmers to try this method of saving their surplus green stuff. Less will then be heard of cattle dying during the winter." In replying to a number of questions, the writer of the paper said it was advisable to chaff maize for ensilage. Whilst cattle would readily eat Scotch thistles when made into silage, this was not the best fodder to put in. It was necessary to weight the pit sufficiently to keep the feed down and the air from getting in. The sweetness or sourness of the outturn was attributable to the temperature at which the silage was kept. A temperature of from 130° to 150° Fahr. would ensure sweet ensilage, but it would be sour if the temperature were from about 80° to 120°. He made a practice of feeding a little chaff with the ensilage. The approximate cost of a pit of the dimensions mentioned in the paper was £65. When the crop was simply stacked, trouble was experienced in weighting. It was not necessary to reweight the pit every time it was used, as by the time the contents were ready for feeding they were set quite hard. Whilst it would be found that some cows would not take to it readily, there was no doubt that it increased the milk supply, and the animals grew to be very fond of it. It was not necessary to damp the fodder in the summer, as there was an abundance of moisture in the crop if cut at the right time. Making ensilage was an excellent way of ridding the land of wild oats.

Narrung, August 24.

PRESENT.—Messrs. Thacker (chair), Sullivan, Barker, Hackett, Williams, Gardener, Critchley, Richards, E. L. Goode, J. and S. E. Morgan (Hon. Sec.), and one visitor.

LUCERNE.—Mr. Bolger contributed the following notes on the cultivation of lucerne:—"Prepare the soil thoroughly by ploughing it deeply and then harrow it down very finely; also roll it well to make a firm bed. Lucerne sown through a drill does best. Sow about 12lbs. to 15lbs. of seed with about 40lbs. of bonedust per acre for cutting purposes. If for grazing, sow about 6lbs. of seed mixed with barley or oats. Lucerne should be sown late in July or early in August, unless put in with a crop, when June is suitable, as the crop protects it from frost. When it is grazed the stock eat the heart out and it becomes very thin. The best seed to use is Hunter River broad leaf. It matures quicker and yields a far heavier crop than any other. Reserve a small plot every year for seed, as seed grown locally is acclimatised, and this means a good deal. It can be stripped with an ordinary stripper. Lucerne prefers deep, loose soil, but will grow well on almost any soil, especially in limestone country. It is one of the finest fodders, especially for dairy cattle. It should be cut one day and used the next; it will then not taint the milk. It is also good for horses as chaff or hay. Breeding sows, fed with a small quantity just before farrowing time, give more milk, and this is very important, as young pigs cannot have too much milk. Where lucerne can be grown in large quantities it will pay better than any other crop. As much as 4cwts. of seed has been taken off one acre. At 1s. 6d. per pound this means a big return, and for hay as much as 10 tons per acre has been cut. Irrigating lucerne will pay well when there is a good supply of water available. Stable manure should be put on as the crop is cut. If it is being irrigated turn the water on at night, not in the day time unless in cool weather." In discussing the subject Mr. Hackett said that if lucerne were sown with the hay it had a tendency to spring up too high, and when the crop was cut the lucerne died back. Where horses had been fed exclusively on lucerne, trouble was experienced with worms. Beef fattened on this fodder did not keep as well as that topped off on the natural grasses. Mr. Jas. Morgan thought 7lbs. per acre quite heavy enough for seeding. Where the seeding was too heavy the plants could not gather sufficient food to enable them to get down to the moisture. It was therefore better to sow less, and, if necessary, add to the crop by broadcasting seed when

the roots of the plants were well down. Lucerne fed to cows before milking left a taint, but when fed after this was not noticeable. Turkestan did not give good results in the district.

Strathalbyn, August 2.

(Average annual rainfall, 19½ in.)

PRESENT.—Messrs. J. W. Fischer (chair), T. Collett, E. Hall, W. Knight, F. S. Traeger, W. Springbett, and J. R. Rankine (Hon. Sec.).

CARE OF HORSES' SHOULDERS.—The following paper was read by Mr. Springbett :—
 “ In submitting this paper to you I am not laying down any hard and fast rule as to the care of horses' shoulders, but give just what my own experience has taught me. The horse is man's best servant, and therefore it should claim the best attention. There is no time at which it needs more care than when it is first put to work. The shoulders of a horse have to stand the brunt of the work, and they are to the horse as a man's hands are to him. The care of the shoulders should begin as soon as the collar is put on. Do not work a colt for more than a couple of hours the first time it is put to it, because it will sweat very much, especially under the collar. Overwork causes the shoulders to scald and blister, and if not well looked after they become sore. Bathe the shoulders with cold water as soon as the animal comes in from work ; or better still, use wattle bark tan, which is made by chopping up a little bark and boiling it in a saucepan with enough water to cover it for an hour ; then strain it, and when cold it is ready for use. Another important point is to use good collars, and I prefer them leather lined. It is better for them to be on the small side than large. The colt can be worked longer each day, and by the fifth or sixth day it can be put to work for a whole day. Watch the shoulders very carefully when breaking in colts, and if there is the least sign of a lump or blister, spell them until they get well again. Once let the skin break and it will take longer to cure and always leave a mark. Some will object that they haven't another horse to take its place ; so the colt is worked on right through the season—seeding or harvesting, as the case may be—to finish up with a raw shoulder, which perhaps has become chronic. This difficulty can easily be overcome if it is in the seeding, ploughing, or cultivating time, by taking off one share of the plough or a couple of tines from cultivator, or working them to a less depth. I would sooner work with a horse less, doing the same work, than work a colt with bad shoulders. Prevention is better than cure every time. If the skin does not break the first week there is not much fear of it doing so afterwards. Any person working horses with sore shoulders is breaking the law. Free horses are more subject to sore shoulders than slow ones, because they sweat more. I find it a good thing to tie a free horse back, and not let him work too hard.”

SOUTH-EAST DISTRICT.

Frances, August 3.

PRESENT.—Messrs. J. C. Brown (chair), Carracher, Meehan, Watts, Baldock, McGillivray, Tompkins, Cooper, Atkinson, W. J. Forster, B. F. Feineler (Hon. Sec.).

SHEEP FOR BINNUM DISTRICT.—Mr. J. McGillivray read a paper on this subject, in which he said—“ The sheep that will pay best to keep on Binnun is the highest class Merino, a fairly plain bodied sheep, with plenty of fold in front, carrying an even wool of good staple, bright and fine of fibre, with any amount of serrations. The finer woolled the sheep the better will it stand the heavy and continuous rainfall and the hot summer of the district. A few years back the Vermont was introduced into the States, and for a while it was a great favorite. The cross undoubtedly weakened the constitution of our sheep, while the excessive wrinkles caused many of our breeders to hark back to the plain bodied animal, and this they were unable to do without sacrificing the original type of bright, fine, lustrous wool with which Tasmania was so long identified before the advent of the Vermont. The class of wool which should and can be grown on Binnun

is the fine Merino. The district will not grow cereals, except perhaps on very small areas in isolated cases. The country is not good enough to profitably raise fat lambs. The cross breeds of sheep return too light a fleece on our light soil. The north of Adelaide Merino, with its coarser fibre and long, loose staple, cannot withstand our continuous heavy annual rainfall. The close and fine-woolled Tasmanian Merino of a few years back, deep of body, short of legs, of good constitution, and almost impervious to wet, is undoubtedly the sheep most suitable for this district." Members generally agreed that more feed and attention were required by sheep carrying a heavy cutting quality fleece, but the results warranted the extra trouble and expense. Sheep in the Binnun country tended to yield a light wool, but the higher prices received for the clean, soft fleeces counterbalanced the loss of weight. Mr. Meehan favored the progeny of Merino ewes crossed with Lincoln rams. The crossbreds and the Merinos did not do well when running together.

Keith, July 27.

PRESENT.—Messrs. Morcombe (chair), Makin, Thompson, Pearson, C. B. Godlee, Hutchings, Fulwood, MacIntyre, Ton, Leishman, Dall, J. A. Lock (Hon. Sec.), and three visitors.

HORSES.—Mr. Makin read a paper on this subject, in which he stated that the best horse for farm work in this district was the medium draught, with plenty of bone and a good action. For breeding, the best sire procurable, not too large and with a good action and style, should be obtained. For roadsters he preferred an animal from a draught sire, with a small head and good action, crossed with a good blood mare. He recommended all farmers to breed their own stock, as it took several years for horses brought from northern districts to become acclimatised. Horses from the South-East were liable to get greasy heels, and their hoofs cracked and broke on the stony ground. In the discussion which followed, Mr. Dall said July was the best time for a mare to foal, as the foal would be ready for weaning when there was an abundance of feed. Mr. Fulwood preferred a clean-legged horse for farm work. Members generally thought that horses bred locally were the best for the district.

Kybybolite, July 25.

(Average annual rainfall, 22in.)

PRESENT.—Messrs. Bradley (chair), G. H. Hahn, C. Hahn, A. R. Scholz, Koth, Lacey, Anderson, Duffield, Schinkel, A. Bradley, jun., C. H. Scholz (Hon. Sec.).

SHEEP-FARMING.—Mr. E. C. H. Schinkel read the following paper on this subject:—"In this district, which is very suitable for the production of first-class Merino wool, sheep-farming does not receive the attention it should. Sheep are not bred for wool-producing purposes alone, many farmers breeding entirely for the export trade; but on the light land around Kybybolite we need not interest ourselves in the latter, as the district is unsuitable for the raising of a carcass fit for export under present conditions. Very few farmers in this district keep an established flock of sheep, nearly all of the flock being for speculative purposes. After a succession of crop failures farmers must realise that a flock of 300 or 400 good bale-filling Merinos would be a great standby. The tendency seems to have been for extensive rather than intensive cultivation, and with too little regard for a good sound flock of sheep. In establishing a flock the class which best suits the country must be ascertained. The required number of ewes should be procured from the man with the best flock in this or a neighboring district, where sheep are raised under similar conditions; and the best method of keeping these sheep in sound condition should be ascertained. In the selection of rams great care should be taken that all are of an even type and quality. This alone is not a guarantee of success. The most important fact is the health of the sheep. It is only the well-nourished and healthy lamb which can be expected to make a good sheep, and to effect this the mother must be in a healthy condition and have an ample supply of milk. This is one of the difficulties experienced in the rearing of early lambs, when there is no green grass about. Owing to the lateness of the rains the season just past has been a striking example. By always having a well-established summer fodder crop, such as kale or chou moellier, this difficulty is very easily overcome. A well-established crop of kale will survive the driest season. This was my experience last year, which was an exceptionally dry one. In this district, where at the best time of the year not a great amount of nourishment is supplied by the natural grass, the growing of fodder crops for summer feed is essential to the success of

sheep-farming. The healthy condition of the sheep is best maintained by a judicious method of feeding. The farm should be subdivided, in order to allow a frequent change of pasture to each flock. Care should be taken not to overstock. An important factor is the constant feeding of salt and sulphate of iron to the sheep. Half a ton of salt and 10wt. sulphate of iron will last 300 to 400 sheep for 12 months. This will cost about 30s. Watering from wells or bores is decidedly preferable to watering from dams or swamps, as in the latter case disease is more likely to be contracted, and in the former minerals supplied in the water are very helpful in keeping the sheep in health. Sheep not only yield wool, but we soon find that it is necessary to sell some of the ewes to make room for the lambs coming on, and a return is secured from this source."

Millicent. August 13.

(Average annual rainfall, 28½ in.)

PRESENT.—Messrs. G. Mutton (chair), H. F. L. Holzgreffe, J. Bowering, J. J. Mullins, H. Hart, H. Oberlander, T. Edgecombe, W. Downs, and H. Day (Hon. Sec.).

LIME.—A discussion took place with regard to the value of lime as a fertiliser. Mr. Holzgreffe considered the land around Millicent contained sufficient lime, but apparently the presence of limestone did not obviate the necessity of providing lime in its slacked state. The Chairman remarked that while farmers in the north of this State almost invariably obtained good crops from limestone country, this was not the case in Victoria, where there was flint limestone. Mr. Hart explained that the lime tended to sweeten the land, and its use in newly drained swamps was very beneficial.

MANURING GRASS LANDS.—Applications of manure to grass lands were best given in the month of August. Generally speaking, where this practice was adopted the lands never needed resowing.

MANURE FOR ONIONS.—The Chairman recommended dressing land in which onions were to be planted with stable manure. The effect of wood ashes also was very good.

MAIZE.—Several members spoke highly of the value of this fodder. To grow successful crops it was essential to keep the land free of weeds. It was liable to be affected by frosts, and Mr. Oberlander mentioned that it had not done well with him on swamp lands.

Naracoorte, July 13.

(Average annual rainfall, 22 in.)

PRESENT.—Messrs. L. Wright (chair), W. E. Rogers, E. Coe, A. Caldwell, W. Loller, A. Langeludecke, jun., C. Bray, J. M. Wray, S. H. Shinckel (Hon. Sec.), and one visitor.

BERSEEM, RYE, AND MANGOLDS.—Mr. Loller exhibited specimens of berseem which he had raised from seed presented to the Branch by Mr. A. Robertson (Struan). There was a good deal of mustard in it. He had also raised some plants from seed procured from the Department of Agriculture. One lot was sown on the 16th April, and came up on the 22nd of April; and the other lot was sown on the 12th of April and came up on the 24th. He had sown a quarter of an acre, and it had stood the frost very well. It made better growth in winter than lucerne. He also showed rye, which was about 3ft. long, and had been fed off. It did very well in this district. He had experimented with mangold tops for feeding off with stock, and they showed good growth for winter.

Wirrega, June 29.

PRESENT.—Messrs. Bice, Purdie, C. and F. Meier, R. Langdon, Fairweather, J. Green, L. Pitman, F. and L. Densley, Exton, Cook, and two visitors.

GRASSES.—Mr. Bice read the following paper:—"This subject has been most ably dealt with at several of the Agricultural Bureau Congresses by gentlemen who have made a special study of it. So far as one can judge, the result has been far from satisfactory in so far as the cultivation of grasses is concerned. Before many years have passed, however, we may be able to show the results of a little labor and care, by the nutritious feed in our paddocks. With our soil of a sandy loam, and the splendid rainfall, also the comparatively late season, this district should be the natural home of grasses. Ultimately mixed farming will be the order, and I consider the fattening of lambs will eventually pay far better than wheat-growing. Firstly, I shall deal with one of, or I might say the

best fodder, viz., lucerne. Both as hay and green feed its fattening qualities are of an extremely high standard. That we can grow this excellent fodder with success has been proved very conclusively by several farmers in the district. Having had some little experience in the Murray Valley with the growing of lucerne, I have observed many points in connection therewith and the extensive tests with the numerous varieties grown on the Government Experimental Farm. Some of the varieties cultivated there are South Australian, Hunter River, Turkestan, Provence, American, Arabian, and Peruvian. Naturally we cannot expect anything like the results that they have obtained, nor perhaps will their best varieties be ours. Last year I tried Arabian, but owing to an extremely dry spring and summer, it died out, or apparently so. This variety is a remarkably quick grower, although perhaps not so good without irrigation as the true Hunter River. I should recommend sowing it broadcast at the rate of 10lbs. to 15lbs. to the acre on well-prepared land, harrowed and rolled after seeding. As we are not able to irrigate, my idea is to sow about 1 bush. of barley with the above amount of seed about May. Some prefer September, but by adopting the earlier sowing the lucerne has a chance of becoming well established before the dry weather comes. Lucerne should be cut when one-tenth in bloom. If irrigated, water a few days before cutting. This prevents evaporation, and the plants move right away after cutting. To sow 1lb. to 3lbs. to the acre of either Turkestan, Provence, or Hunter River with the wheat would not only improve our lands—as it is an excellent fertiliser—but would increase the carrying capacity of our stubble paddocks. Turkestan is a cheaper variety, and stands grazing much better than the others. Prairie grass is a perennial and a splendid fodder, which grows during our winter months when the natural grasses are dormant. In Western Queensland, on heavy black soil it grows most luxuriantly. They simply sow it, as all their other grasses, on the ashes, without the slightest cultivation. So far it has only grown to about 9in. or 10in. high with me, but I intend this year to dress a plot with super. Previously it has had blood manure applied at the rate of about 70lbs. to the acre. The South-East has been recommended to sow brome grasses. One of the varieties (Hungarian brome) under experiment on poor sandy land has thrived remarkably well, making a dense succulent turf about 1ft. high, and standing drought well. When once established it appears to be hard to eradicate. Rhodes grass is a very valuable fodder, but I would not recommend growing it on our lighter soils. It should do well on the red loam, and it makes a very heavy growth on good heavy land. Red fescue has been described as a vigorous, tall grower 3ft. to 4ft. high, exceedingly hardy, and yielding a heavy cut of hay. It succeeds best on comparatively wet lands. Cocksfoot has been proved in this district. It makes a rapid growth after early rains, and is one of our most valued grasses. It has been known to grow 23in. in eight weeks, and should do well on lands that are well drained. So far as one can judge of the various grasses tried down here, this must take the place of pride. Its feeding value is of a very high standard. It should be sown as soon as possible after the first rains, at the rate of about 20lbs. to 30lbs. to the acre. Of the rye grasses I prefer Perennial, which is a quick and early grower, and also very nutritious. Small quantities should be sown with other varieties. *Pasp. dilatatum*, or golden crown grass, so far as I can judge, has not been a success here. I consider that when our red land has been cleared and well cultivated it will do far better than on the more sandy soil. No doubt this is quite the best known of our grasses. The name 'drought grass' which it has gained, speaks for its hardiness. It is most nutritious, will stand the rough time the stock give it, and responds quickly after a summer rain. If allowed to seed it spreads very rapidly, and is one we might class as purely a summer grass. Perhaps the reason of the poor germination of the seed is that the grass ripens unevenly. It pays to procure the best seed; the initial expenditure is amply repaid in the germination. *Paspalum* germinates in from seven to 21 days, and needs both heat and moisture, but it can be sown in our early winter without detriment to the seed. It has been known to germinate after being in the soil for two years. Sow broadcast, 6lbs. to 10lbs. per acre. *Panicum crus galli*, or barnyard grass, makes a most prolific growth, especially under irrigation. I have fed this grass to cows with marked success. It is a rapid grower after being fed off. The hay, though on the coarse side, is readily eaten by stock. Owing to the dryness of last spring my plants died off before maturing, but they made rather a good growth the first year. Sow 5lbs. per acre. *Phalaris commutata* is a splendid winter grass. At Brimbago, also at Messrs. Langdon Bros., it has made rather a good stand. The field test has yet to be made; nevertheless, on well cultivated land I feel confident it will prove one of our best winter grasses. It stands the most severe frosts, and is in every respect a most hardy grass, yielding a rich herbage, of which stock are very fond. It stands grazing very well. Veldt grass, a very hardy perennial, grows rapidly after the first rains, but dries off in the latter part of spring. It grows where other grasses fail. It has made

splendid growth in the Pinnaroo district. Stock are very partial to it, both in its dry and green state. Rib grass makes a really good growth during the early summer. It may be seen at its best at the foot of Mount Lofty Ranges. Stock eat it readily." A good discussion followed the reading of the paper.

Wirrega, July 27.

PRESENT.—Messrs. Exton, Bice, M. and J. J. Green, F. and A. Densley, F. and E. Meier, Purdie, L. Pitman, Cook (Hon. Sec.), and one visitor.

THE PRESERVATION AND CARE OF HARNESS.—Mr. M. Green read the following paper : —“As you are all well aware, harness is expensive, and great care should be taken with it from the first time of using. Give due attention to all leather by protecting and housing it in a proper manner. First of all clean it regularly. The best way is to wash with soft-soap and warm water. Unbuckle all straps and clean thoroughly under the buckles, as rust and sweat are the worst enemies of leather. When dried off, apply a dressing made as follows :—1 quart cod liver oil, 1lb. tallow, $\frac{1}{2}$ lb. beeswax, melted together. If for buggy harness, and a good polish is required, add to the foregoing $\frac{1}{2}$ lb. of vegetable black, 1oz. turpentine, and increase the amount of beeswax to $\frac{1}{2}$ lb. Do not at any time hang harness in the stable, as the ammonia fumes rising from the manure badly affects any class of leather. We all hang collars and winkers so that they are handy, but if we keep the harness out of the stables I am certain we shall save pounds in the course of a few years. Keep a ball of wax, hemp, and flax, and a few awls and saddlers' needles handy, as material must wear in time; but if taken in hand immediately much will be saved. I would also advise all of you to use the keepers which are placed on the hames straps. How often are the hames just buckled and the end of the strap left hanging loose. This looks very sloppy and untidy, and the keepers are put there for a purpose.”

LOSS OF A HORSE.—Mr. J. Green gave an account of the illness and treatment of one of his horses, and also of a *post-mortem* examination held on same. The horse showed every symptom of suffering from internal parasites, and was vigorously treated with tartar emetic and other worm cures. The animal was also treated for sand, but without result. The *post-mortem* revealed that parasites were present in enormous numbers, and members were puzzled that the treatment did not shift any of them.

Daisy Queen—1st Three-year-old Shorthorn Cow at the 1910 Show of the Royal Agricultural Society at Liverpool.

AGRICULTURAL PUBLICATIONS.

The following publications have been issued by the Department, and are available for distribution at prices mentioned:—

Pruning of Fruit Trees, by G. Quinn, 1s. 3d.; posted, 1s. 7d.

Vinegrowers' Manual, by A. Sutherland, 6d.; posted, 7d.

Reports of Conferences of Australasian Fruitgrowers held at Brisbane and Wellington, 1s. each, or 1s. 1d. if posted.

Journal of Department of Agriculture of South Australia, 1s. per annum in advance: 3d. per single copy to residents of South Australia; 2s. 6d. per annum to other places.

Any of the following Bulletins and Leaflets may be obtained by sending a penny stamp for postage:—

Agriculture, Miscellaneous: Agricultural Bureau Congress Reports; Agricultural Experiments; Amount of Spirits to be Extracted from a Ton of Raisins; Depth of Sowing of some Agricultural Seeds; Hints to Intending Irrigationists; Housebuilding in New Districts; Lucerne Cultivation and Management; Lucerne Harvesting; Milling Characteristics of Australian Wheats; Milling Experiments; Milling Qualities of South Australian Wheats; Reclamation of Land; Roseworthy College Farm Flocks; Roseworthy College Harvest Reports; Roseworthy College Permanent Experimental Field; South Australian Wheat Yield, 1907-8; Stage to Cut Wheat; Hay; Trial of Stone-Gathering Machines; Salvation Jane or Paterson's Curse.

Horticulture: Apple Mussel Scale; Bordeaux Mixture; Cidermaking; Curculio Beetle; Codlin Moth; Currant Industry; Defects in Export Apples; Fertilisation of Orchard Lands; Fruit Drying; Fruit Flies; Fruit Preserving; Grape Vine Mildews; Gumming Disease of Peach and Almond Trees; Selection and Planting of Fruit Trees; Irish Potato Blight; Peach Leaf Curl Fungus; Plums and Prunes; Preserving, Canning, and Drying Fruits; Production of Early Tomatoes; Remedies for Diseases of Fruit Trees and Vines; Some Notes on Almonds.

Dairy: Milking of Cows; Spaying of Cows; Taints and Flavors of Dairy Produce.

Stock: Branding of Stock; Stomach and Bowel Diseases of the Horse.

[Every farmer and fruitgrower should join the Agricultural Bureau. Write to Department of Agriculture for particulars.]

Minister of Agriculture.

POINTS FOR PRODUCERS.

Agricultural Bureau.

The Annual Conference of the Hills Branches of the Agricultural Bureau will be held at Meadows South on Monday, October 21st, commencing at 10-30 a.m. The opening address will be delivered by the Hon. T. Pascoe, M.L.C., Minister of Agriculture. An interesting programme is being arranged, including papers by Messrs. C. Ricks (Cherry Gardens) and H. F. Rollbusch (Woodside Branch). The officers of the department who, it is anticipated, will deliver addresses are Messrs. George Quinn, Chief Horticulturist; P. H. Suter, Dairy Expert; and Veterinary Surgeon F. E. Place, M.R.C.V.S., B.V.Sc. There will be ample opportunity for questions and discussion. The Meadows Branch has the management in hand, and the usual arrangements have been made for refreshments to be supplied by a caterer.

Lands for Settlement.

Referring to the opening up of new land, the Premier in his Budget speech stated:—"Surveys are in progress in the vicinity of Weedina and Minnipa Hill, where four survey parties are engaged; in the hundred of McLachlan, about 40 miles east of Elliston; in the Darke's Peak country; north-west of Franklin Harbor; on the Tailem Bend and Brown's Well railway line; and the commonage lands in the South-East. The area now under survey is about 735,000 acres, on which 15 surveyors are engaged. A considerable portion of this land should be available for offer during the present financial year. The area of land open to application on June 30th last was about 220,000 acres, in various parts of the State. It is anticipated that three new hundreds along the Tailem Bend and Brown's Well line will be gazetted open to application during the next few weeks."

Land Allotted.

In the course of his Budget speech the Premier (Hon. A. H. Peake, M.P.) said:—"The total area surveyed during the year amounted to about 647,700 acres; 531,588 acres of Crown lands were allotted to 462 applicants (average to each 1,151 acres); 1,247 acres of homestead blocks were allotted to 77 applicants (average to each 16 acres); and 75,573 acres of repurchased lands were allotted to 357 persons (average to each 212 acres). The last mentioned area includes the Moorak Estate No. 2, part of which was subdivided into small blocks, some comprising only half an acre, for residential or business purposes. The total number of allottees for the whole area disposed of (608,408 acres) was 896."

Quality in English Wheat.

At a conference of agricultural teachers which met at Cambridge on July 18th, Professor R. H. Biffen read a paper on "Quality in Wheat," in which he stated that the appearance in the British market of the Canadian wheat, "Manitoba Hard," and the improvements in milling processes have set up a new standard of quality for baking purposes. Rating the best Canadian wheat at 100, a good average flour wheat now in general demand for bread-making might be reckoned at 80; while to ordinary home-grown wheat, the highest figure that could be assigned was 60. As a consequence the British miller was forced to use a large admixture of foreign wheat, otherwise his flour was unsaleable. Professor Biffen stated that "strong" foreign wheat may be worth to the inland miller as much as 10s. per quarter more than the home grown. The Home Grown Wheat Committee have conducted a long series of experiments with the object of discovering what steps should be taken to produce strong wheat in England. It has been shown that neither soils or manure are capable of raising the baking quality of ordinary British wheat above 70, and that improvement must be sought in the introduction of new varieties. Wheats from all parts of the world have been tested, with the result that only one wheat (of the varieties in general use), namely, Red Fife, has been found to retain its strength under all conditions of soil and treatment. Unfortunately, in most parts of the country this variety is such a poor cropper that it is quite unsuitable for introduction.—*Journal of Board of Agriculture.*

Alfalfa.

About the most gratifying sight to the Californian eye these days (says the *Pacific Rural Press*) is the alfalfa crop. There is no green so richly beautiful as that of an alfalfa field; there is no harvest so absolutely satisfying as the long rows of new-cut alfalfa hay. That crop means beef and pork, milk, butter, and cheese, the absolute staples of life. It means a soil not exhausted but enriched by the growing of the crop; it means so much addition to the world's nutriment, caught freely out of the inexhaustible air. It means the one crop which cannot be overproduced, the staple of more varied uses than any other known product. If the water lasts, good alfalfa land now will be good alfalfa land still a million years from now, without ever drawing on anything but the air for fertiliser. If in time beef becomes too scarce and dear for the common food of the people, there will still be cheese—a food quite as nutritious and, when properly prepared, quite as palatable and digestible. And the alfalfa fields can furnish us plenty of cheese and butter, and some beef, forever. Alfalfa utilises the soil 12 months in the year, and produces as many crops as water and sunshine will allow. It is both beautiful and practical, profitable and inspiring. And all we can get out of it will be only just enough.

The Pending Wool Shortage.

That the world is not producing enough wool to satisfy a constantly increasing demand is obvious, says the *Chicago Breeders' Gazette*. Present prices are not only legitimate, but further appreciation will merely verify trade forecasts. As there are annually more mouths to eat meat, so there are more backs to cover, and the wool-producing regions have been reducing rather than expanding flocks. The celerity with which the 1912 wool clip has passed out of growers' hands reveals manufacturers' needs. What the shortage in the domestic clip actually is can be only estimated, but buyers place it all the way from twenty to thirty million pounds. In many sections they have not found 50 per cent. of the amount they have been able to purchase in recent years. The statistical position of the wool market is decidedly strong.

Dried Strawberries.

J. C. F. Holcomb, a berry grower of White Salmon, Washington, has discovered, after many experiments, a sun-drying process for strawberries which has proven so successful that he now receives orders for the product from many States in the Union, and also from Alaska. It is said that he intends later to organise a company and turn out the fruit on a large scale.—*Californian Fruit Grower*.

Australian Sheep in South Africa.

According to South African Customs figures, the value of sheep received by that country from Australia since the year 1906, inclusive, is no less than £123,146, and represents in round figures 29,300 animals. As could only be expected, rams have largely preponderated in these imports, and, says *The Wool Record*, it needs scarcely a moment's reflection to see what an immense influence this new blood must be having upon South African sheep and wool.

More Brain—Less Sweat.

Abraham Lincoln said 60 years ago that a man was foolish to walk all over 40 acres when he could raise the same crop in 10 by intensive cultivation. It is not so necessary that the farmer should plant more acres or work harder, but it is only common sense for him to use modern scientific methods instead of his grandfather's old "rule of thumb" and his grandmother's old rule of the "dark of the moon." The modern idea is to save work and get larger results; to better the quality and to make more money. If every farmer should grade and select his seed; should grade and clean the grain he markets, and should feed the screenings on the farm, the price of every grain would go up and stay up.—*Campbell's Scientific Farmer*.

Agricultural Ireland.

Oats, not potatoes, occupy the largest acreage in Ireland. About 1,000,000 tons, chiefly black oats, are produced annually. The Irish potato crop generally exceeds 3,000,000 tons. Irish potatoes hold the first place on the British market. Ireland also supplies the British market with most of its cattle, over 800,000 head being exported to Great Britain in 1909. Half of the Irish exports are young animals, which are fattened in England and Scotland; in fact, the chief Irish export is cattle. After livestock, butter is the chief export. The butter trade is valued at about 20,000,000 dollars per year.

Beet-tops for Cows.

There are dairymen in California who maintain that sugar-beet tops make one of the best feeds available for the production of firm butter. These tops consist of the leaves and the crown of the beetroot, says *Hoard's Dairyman*. Analyses of these tops prove that water constitutes about seven-eighths of the aggregate substance. One hundred pounds of fresh tops are found to contain 8.25lbs. of digestible nutrients composed as follows :—Protein, 1.71lbs.; carbohydrates, 6.49lbs.; fat, .05lbs. Beet tops alone will not make a balanced ration, or anything near to it. They can only be used as a portion of an animal's forage ration.

The Needs of Lucerne.

Regarding the needs of lucerne, the *Agricultural Gazette* says, we could almost sum the matter up in four words—lime, drainage, humus, and inoculation. Perhaps we have given these in the order of their relative importance. Lime is necessary on soils not naturally of limestone formation or filled with limestone pebbles. The importance of this is impressed on us more and more each year; in fact, we believe to-day that there have been more failures throughout the United States on account of insufficient lime in the soil than from any other cause. Then as to drainage, there is no use in planting lucerne on any soil where water may ordinarily be found at a depth of less than 3ft. The lucerne may grow all right until its roots strike this water, but then it will die. Fertile soils contain enough humus. Impoverished soils may be so deficient that special preparation must be made before lucerne can possibly succeed. Where stable manure is not available on impoverished soil we would recommend preparation for lucerne one or two years in advance, growing such crops as crimson clover, mammoth clover, cow peas, field peas, or soya beans, and preferably turning them under or else pasturing them off, so as to give the soil the greatest benefit possible from them.

Local Improvement Clubs.

Co-operation (says the *American Agriculturist*) has been the keynote of most of the rural advancement that has been so marked in the last decade. The people are learning how to get together in an effective way for the promotion of a definite object. Automobile clubs in small towns have been effective for securing better road and bridge conditions merely by intelligent co-operation with the farmers and landowners of the surrounding community. The numerous farmers who own automobiles have quite naturally joined with these village associations; result, more practical road work is being done every year from local initiative. The development of neighborhood social centres and neighborhood clubs both among farm men and farm women have in many notable instances secured important and permanent improvements for the whole community. The centralised country high school is frequently becoming a neighborhood centre for meetings of all kinds, and from these local civic centres movements have been inaugurated and directed which have had township-wide and county-wide influence for betterment. Generally, the less formal and binding the form of the organization the more satisfactory are its workings. The mere fact of getting together for an exchange of ideas and for mutual enjoyment and betterment is a vital factor. The neighborhood club under whatever name it may exist is fulfilling a long-felt need in neighborhood affairs and will prove a desirable influence in any rural community.

Protein in Alfalfa Hay.

That alfalfa hay contains more pounds of protein for each 100lbs. than any other kind of cured hay, and also contains a large amount of carbohydrates, are interesting facts brought out by a new bulletin of the College of Agriculture of the University of Wisconsin. Alfalfa contains 11lbs. of protein for each 100lbs. of hay; while alsike clover contains 8lbs.; red clover 7lbs.; and barley hay 5lbs. Other hays, such as redtop, Kentucky bluegrass, Timothy, and oat hay, contain less than 5lbs.

Boys' and Girls' Clubs in Iowa.

The United States Government is to co-operate with the Agricultural Extension Department of Iowa State College in making the boys' and girls' club work in Iowa the greatest of its kind. Prof. W. J. Kennedy, head of the Extension Department, has just closed an arrangement with the Department of Agriculture at Washington whereby the college will receive 1,000 dollars annually for the salary of an additional worker among Iowa boys and girls, 300 dollars annually for travelling expenses, and the franking privilege for all official bulletins and circulars sent to the boys and girls as

part of their study work. This year something like 15,000 boys and girls are enrolled in the study clubs. They are growing corn, cultivating gardens, raising poultry and pigs, cooking, sewing, and doing housekeeping. All their work is done under supervision and it will close with the annual contests at the short course at the college in January. With the help now provided Superintendent Bishop, in charge of the work, hopes to organise 10,000 more boys and girls in another year.—*The Breeders' Gazette*.

Flaxseed.

As a grower of flaxseed, Argentina holds first rank among the five countries—Argentina, Russia, British India, United States, and Canada—which produced the commercial crop of the world. Sown in May and June, the plants occupy the soil during the Argentine winter and are for the most part cut in November and December, the close of the transequatorial spring and beginning of summer. Flaxseed has virtually no use other than for the manufacture of linseed oil and oil-cake. The Argentine seed-crushing industry is insufficient for domestic needs and an average of upward of 100,000galls. are imported annually from the United Kingdom and France. The exports of flaxseed from Argentina in late years have been heavier than those from any other country. About 3,209,000bush. of Argentine seed were taken by the United States alone in the year ended June 30th, 1910, and of the 6,291,000bush. imported in 1910-11 a heavy proportion came from the South American producer.

Handling Young Pigs.

When the suckling pig gets about three weeks old, says a writer for the *Texas Farmer*, he will usually begin to notice his mother's feed. Then is a good time to make a little separate pen for him with a creep hole to it, so the pig can get in and eat without being disturbed by its mother. Skimmed milk mixed with wheat shorts and a little fine ground corn is about the best thing to start the little pigs eating on. Soaked corn will also be usually eaten readily, but there is nothing that is quite as satisfactory at this time to get the pig started on as milk. Be sure the little fellows are eating well and are not depending much on the dam for milk before weaning. If they are just nibbling around the trough and are depending mostly on their dam for a living they will receive quite a set-back, and maybe the smallest ones will die when the sow is taken away from them. Right at weaning time is a very critical period in the pig's life, therefore a little extra care at this time will pay royally. If handled well they will never lose their baby fat and will make the best gains for food consumed of any part of their lives, but if they are stunted it will take lots of time and patience to get them to growing again, and it is very easy to stunt them.

Imports and Exports of Plants.

During the month of August, 9,232bush. of fresh fruits, 3,602 bags potatoes, 427 bags of onions, and 150pkgs. of plants were examined and admitted at Adelaide and Port Adelaide under the Vine, Fruit, and Vegetable Protection Act of 1885; 88bush. of bananas (chiefly over-ripe) were rejected. Under the Federal Commerce Act, 1,096 cases of fresh fruit, 2,660pkgs. dried fruit, 62pkgs. preserved fruit, 8pkgs. plants and seeds, and 100pkgs. honey were exported to oversea markets during the same period. These were distributed as follows:—For London, 128 cases oranges and 2,401pkgs. dried fruit; for South Africa, 225pkgs. dried fruit; for Germany, 100pkgs. honey; for India and East, 670 cases apples, 62pkgs. preserved fruit, 15pkgs. dried fruit, and 1pkg. trees; for New Zealand, 298 cases citrus fruits, 19pkgs. dried fruit, and 7pkgs. plants and seeds. Under the Federal Quarantine Act, 633pkgs. plants, seeds, &c., were admitted after examination from oversea sources. During the month of September, 12,007bush. of fresh fruits, 747 bags of potatoes, 283 bags of onions, 32pkgs. vegetables, and 24pkgs. plants were inspected and admitted at Adelaide and Port Adelaide under the Vine, Fruit, and Vegetable Protection Act of 1885; 368bush. of bananas (chiefly over-ripe) were rejected. Under the Federal Commerce Act, 861 cases of fresh fruit, 103pkgs. of preserved fruit, and 2,441pkgs. of dried fruit, and 1pkg. plants were exported to oversea markets during the same period; These were distributed as follows:—For London, 41 cases of oranges and 2,239pkgs. dried fruit; for South Africa, 197pkgs. dried fruit; for New Zealand, 538 cases citrus fruit, 201pkgs. dried fruit, and 1pkg. plants; for India and East, 280 cases apples, 2 cases oranges, 103pkgs. of preserved fruit, and 1pkg. dried fruit. Under the Federal Quarantine Act, 544pkgs. plants, seeds, bulbs, &c., were introduced from oversea markets.

ALLENDALE HOMESTEAD, OODNADATTA.

INQUIRY DEPARTMENT.

Any questions relating to methods of agriculture, horticulture, viticulture, dairying, &c., diseases of stock and poultry, insect and fungoid pests, the export of produce, and similar subjects, will be referred to the Government experts, and replies will be published in these pages for the benefit of producers generally. The name and address of the inquirer must accompany each question. Inquiries received from the question-boxes established by Branches of the Agricultural Bureau will be similarly dealt with. All correspondence should be addressed to "The Editor, *The Journal of Agriculture*, Adelaide."

STOCK INQUIRIES.

(Replies supplied by Mr. F. E. PLACE, M.R.C.V.S., B.V.Sc., Veterinary Lecturer).

Is Meningitis in Cattle Contagious?

A member of the Minlaton Branch of the Agricultural Bureau stated that some time ago he had a cow which showed symptoms of meningitis. He asks if there is a danger of the rest of the herd becoming affected.

Reply—Some forms of meningitis in cattle are contagious, but with the exception of the tubercular form those found in South Australia are as a rule not so. Should other animals show symptoms, bonemeal and salt, either as a lick or in 2oz. doses daily, would very likely act as a preventive.

Removal of Callous Growth.

"E. J. M.," Angas Plains, asks—(1) I have a young horse with a callous lump under the jaw, resulting from strangles 12 months ago; should it be cut out? (2) Would a filly with hip down do for breeding purposes?

Reply—(1) Cutting out is probably not necessary. Try rubbing in daily for 10 days oleate of mercury 10 per cent., and give $\frac{1}{2}$ dram iodide of potassium in a little drinking water once a day for 10 days. (2) Hip down, if accidental, is not likely to be transmitted to offspring.

Strangles.

A member of the Belalie Branch has a one-year-old horse that, following on strangles, has a suppurated swelling under the jaw; the animal is gradually wasting. He asks for advice as to treatment. Another member has a two-year-old colt which has been wasting for about eight months. There is no running from the nostrils, and the eyes are bright, but its head is a little swollen.

Reply—(1) The continued form of strangles described is fairly common ; abscesses form in different parts of the body, and the disease lasts for many months. Two grains of iodide of arsenic in 20 grains of sugar of milk twice a day on the tongue for some days would probably improve matters. (2) The symptoms of the two-year-old colt point to bloodworms. Half an ounce of Fowler's solution of arsenic twice a day in a little bran, continued for a week, stopped for a week, and repeated for a second week, will probably cause an improvement.

Supposed Blood Poisoning.

" H. H. O.," Glencoe, had a foal which prior to being weaned was in the pink of condition. On being taken from his mother he was placed in a paddock—low, flat country, but thought to be healthy—and every second day at first given a feed of good oaten chaff, and then twice a week. One side of his head became swollen, and afterwards the swelling extended all over the head. He was unable to eat, but drank freely. The animal did not appear in much pain, and was given a little saltpetre, but the swelling spread all over the body, and just before death, seven days after the swelling was first noticed, the eyes protruded very much.

Reply—From the symptoms described the foal probably died from a form of blood poisoning called *purpura hæmorrhagica*. Saltpetre is not a very good thing for this complaint. Sulphate of quinine in 15 grain doses three times a day on the tongue is better.

LATE HATCHING, &c.

" White Leghorn " asks—(1) What are the general causes of late hatches ? (2) In scratching sheds what space per fowl should be allowed ? (3) Is the dry mash method of feeding advisable ?

Reply—(1) Several breeders have reported that the eggs placed in incubators this season are hatching, as a rule, a day late. This refers to various makes of incubators, including those you mention. No trouble in this respect is experienced at the three Government Poultry Stations, where the breeding stock are housed under varying conditions, including confinement in scratching sheds. This trouble has often been experienced by breeders in other seasons, and is probably due to abnormal seasons affecting the stock. In many cases the stock itself is to blame, and in other cases the methods adopted (feeding, etc.). (2) In large American scratching sheds the floor space per fowl works out at 3·4ft. Should recommend 4ft. to 5ft. here. In such cases, however, there should be a cement concrete floor, overlaid with 6in. of sandy loam, and then the scratching material (short straw) on top. (3) *Re Dry Mash*.—In this form of feeding the stock must be reared on dry mash and grain, &c., fed in suitable hoppers. Americans claim that the smaller number of eggs laid is more than counterbalanced by saving in labor. The whole question, however, requires careful experiment under our conditions, because there are

questions other than those relating to mere numbers of eggs to be considered. Theoretically the system is sound as regards the mechanical act of feeding. The dry feeding method has many friends in Victoria, and the results financially, and appearance of the stock, seem to justify its adoption.

MANURING ORANGE TREES.

“W.D.” asks—“Is it beneficial to put superphosphate around orange trees?”

Reply—“Superphosphate may be applied to orange trees with safety, and usually to advantage, using from 1lb. to 6lbs. per tree, according to size of same. The fertiliser may be sown thinly around the tree, taking in an area extending from near to the stem to a distance of several feet outside the spread of the branches. This should be done in the winter just before digging the soil. It is not too late to apply it now where irrigation is practised through the summer.”

GREEN FEED FOR COW.

A Wallaroo correspondent seeks information respecting the growing of green feed for a cow, &c.

Reply—Mr. G. Quinn, Horticultural Instructor, writes in reply—“I beg to advise you try lucerne instead of mangels, as you will obtain on the average a quicker and larger and more nutritious fodder therefrom. If you have an area 50ft. or 70ft. square, prepare the land at once and sow the seed straight away. The soil needs to be worked up, manured, and then tilled down to a fine loose condition—like a well-worked fallow field. Sow about 2lbs. to 3lbs. of seed on the area mentioned above and use from 20lbs. to 28lbs. of superphosphate when preparing the ground. Sow the super. over the ploughed or dug ground, and then mix it into the soil when harrowing. After sowing the seed cover it over very lightly by dragging a light harrow or tree-bough or rake over the surface. If you have any loose horse manure spread it thinly over the surface to keep the soil from crusting. If the soil be moist the seed will germinate without water; if it be dry apply water through a sprinkler or hose. The sprinkler is best, as it showers the drops gently and does not crust the soil like a thicker body of water. Always cut the lucerne systematically and feed to the animals; do not let them graze upon it. Always apply a watering to the ground, either just before or just after cutting a patch. Never let lucerne seed form, but cut it at the flowering stage, and if you do not want it at once, dry it for hay, of which it makes the very best. *Re* peas. It is too late to sow garden peas now, but you could sow Canadian Wonder dwarf beans, cucumbers, melons, marrows, &c., and sow or plant out tomatoes in your vegetable garden.”

GRAPE VINE PRUNING FOR AMATEURS AND BEGINNERS.

By GEO. QUINN, Horticultural Instructor.

(Continued from page 139, September issue.)

SPRING AND SUMMER PRUNING.

Under this heading is classified all of those operations performed upon the vine after the period of vegetative activity begins. Taken in general there is a great diversity of opinions expressed upon the necessity or even the utility of the practice by those engaged in the cultivation of grape vines. The practical men usually contend that it is necessary from economical reasons, putting forward that it is desirable to restrict the spread of the plants, or that it is needed to increase the setting or the size and color of the fruits. On the other hand, the more scientifically informed argue that not only is it not necessary and avoidable but distinctly injurious, if pursued for a lengthy period on the lines frequently adopted by vigneronns. As the object of these notes is to assist in guiding the beginner along safe lines from the inception of his vine-growing, the writer unhesitatingly supports the side taken by the scientific men.

The part played in the economy of a plant by its green chlorophyll bearing portions should ever be kept in mind in all of the practices followed in vine cultivation. This consideration should even begin with the setting out of the plants, inasmuch as the judgment displayed in deciding the distances apart to place them will aid materially in rendering unnecessary much of the rough restriction of the growing canes now practised.

The leaves are, in function, the lungs and stomach of the plant, and in so far as its powers of respiration and assimilation are reduced by their removal so is the vine checked and weakened. In the leaves is manufactured the starch, which is afterwards changed into sugar, a large portion of which finds its way into the fruits. Hence, the removal of healthy leaves retards the production of this very essential constituent.

Spring and summer pruning as practised here has been said to consist of three operations, viz.—(a) Disbudding, (b) pinching, (c) topping.

The first-named is defined as the removal in the very early stages of their development of all watershoots and other superfluous growths from amongst those found upon the fruiting canes. This is done with a view to concentrating the energies of the plant into those shoots deemed to possess the greatest present and potential value. It is applied also in connection with the training of vines under certain systems, such as in the manner described in these notes, in shaping the various spaliers and cordons.

The second operation, called "pinching," has been utilised in the direction of removing the sappy terminal points of the flowering canes to induce the setting of the fruits through the temporary check which such an action imposes at that period upon the vigor of the shoot, as well as in stopping the leader in the formation of the main arms of the Thomery spalier.

The third operation, which has been referred to as "topping," consists of an indiscriminate lopping off of the upper portions of the growing shoots to a length of several inches and not infrequently to that of a foot or more. This procedure has been followed largely to enable the implements of tillage to pass without hindrance between the rows of vines. The practice has been widely denounced by those whose opinions are entitled to respect. Quite apart from its weakening influences upon the vines, anyone who, in the winter following upon its application, proceeds to prune the vines is met with a tangle of laterals of a particularly annoying character. Should the variety need rod-pruning the results of such a topping are disastrous to his chances of securing good fruiting canes.

In respect to these operations the beginner is advised to proceed with caution upon the following lines :—

DISBUDDING.

In the production of some sorts of table grapes and Muscat raisins it has been found necessary, in order to secure fruit of the highest quality, to prune the vines in winter to a limited number of spurs, each possessing one or two buds only. The effect frequently observed to follow upon this procedure is the starting into activity of a fairly large proportion of watershoots on the old wood, as well as buds in the angles made where the spurs join the older limbs. In manipulating the watershoots, all of those arising from the main stem, whether they emerge above or below the soil line, should be rubbed away while yet in the brittle stage. Those starting from any of the main or secondary arms should be considered in the light of their possible value in renewing the arm, as explained in the earlier chapters on winter pruning. Should there be indications of the necessity for their early use, such as are well situated should be saved until the next winter season determines this point. The shoots arising out of the angles where the spurs join the older wood or secondary arms are not truly watershoots, and their closer junction

with the old wood may render some of them of value to work upon at the next winter's pruning.

PINCHING.

This operation does appear to secure a certain amount of increase in the setting of the berries on the bunches formed upon some grape vines, and the check administered to the shoots is so mild and temporary in character as to render its devitalising influences a negligible factor.

TOPPING.

Where the vines are pruned with good judgment in the winter, and disbudding has been reasonably applied, there should be no need for topping, even when the plants are growing strongly in rich soil. Shoots which threaten to spread across the spaces between the rows should be bent or tied to the trellis wires. In the case of bush vines only the extreme tips need cutting, if any shortening be found necessary to permit unrestricted use of the tillage implements after midsummer.

CINCTURING OR RINGBARKING.

This important method of restricting the activities of some varieties of grape vines, to induce a more consistent setting of the berries upon the bunches, is a form of spring pruning. The cincture, which consists of completely removing an extremely narrow ring of bark from around the stems, main arms, or even canes of the vines, is performed when the corollas are falling (see (2) and (3) Fig. 43) from the blossoms. The immediate effect of this

Fig. 42.—Vine Stem showing Cincture.

is to impede to a large degree—for a short period only—the return of the elaborated sap from the foliage to the root system and thus prevent or check the rapid extension of the roots, which naturally takes place during the first few weeks of returned animation in the spring. This retention of the elaborated sap causes the stem immediately above the cincture to become increased

Fig. 43.—Stage of Flowering when Cincture is applied is indicated in (2) and (3).

in diameter, and apparently the meagre circulation of sap allows the berries to make good their connection with the pedicels and become an integral part of the bunch. It is desirable that this checking of the sap should not be of too prolonged a character. Experimental tests indicate that it is essential the disconnected tissues should again bridge over the wound, and thus enable

Fig. 41.—Cinctured Stem showing Waxed Bandage and Cincture callused over in Six Weeks.

the circulation to resume its customary course at an early date. If a complete ring of bark, not more than one-sixteenth to one-twelfth of an inch wide be removed (as shown in Fig. 42), the chances of this taking place quickly are increased.

Some currant-growers claim to have obtained equally good results from the use of a simple incision made by passing a sharp knife around the limb, but the general opinion favors the removal of the narrow ring of bark. To secure the rapid bridging of the wounded tissues it is desirable to protect

(a)

(b)

Fig. 45.—Comparison of Fruit Setting on (a) Cinctured and (b) Uncinctured Vines.

the cut section against the drying effects of sun and wind. Some growers do this by means of strips of bagging or rag bound around the cinctures. Better results, however, may be secured by the use of strips of calico about an inch wide which have been steeped in grafting wax, as indicated in Fig. 44.

In the tests from which these figures were made the waxed bands enabled the healing callus to completely fill the wound within six weeks, and the nourishing of the fruit and foliage proceeded in a normal fashion. Glancing at Fig. 44, just above the cincture which has been covered by a waxed band,

may be seen the cincture of the previous season, which had not been covered, and it has become dry, and only partially healed.

Currant vines cinctured too severely indicate the devitalising effect of the operation in failing to ripen the terminal portions of the canes, sometimes for a couple of feet in length. In Fig. 45 the comparative effects of the

Fig. 46.—Types of Vine-pruning Shears.

cincture in causing the setting of the berries on bunches of the Zante currant is shown. Although primarily applied to the Zante currant, the cincture has been applied to Sultana and Gordo Blanco vines with promising results in the setting of the fruits. In the case of the former, however, it has been

chiefly applied to the fruiting canes, as opposed to being made upon the main stems or main arms of the Zante currant.

VINE-PRUNING SHEARS.

Fig. 46 depicts two types of shears used in vine pruning. Both of these have wooden handles, to enable the pruner to retain a firm grip when severing strong shoots. Another form of the lower pair of vine shears which is used in this State, but not illustrated here, is not provided with these wooden grips, but has simply the rounded steel handles, the end of one being drawn out a little longer into a flat steel chisel-like point, which is sharpened. This chisel is designed for stabbing off watershoots or suckers. In cold weather when the hands of the pruner are chilled, he experiences some difficulty in retaining a good hold of these steel handles, and it is a common practice to sleeve a short piece of $\frac{1}{2}$ in. rubber hose over each of the steel handles to make a non-slipping grip.

ANALYSES OF FERTILISERS.

The following are further results of analyses made by the Government Analyst (Mr. W. A. Hargreaves, M.A.) of samples of fertilisers taken since the beginning of the year :—

GEO. QUINN, Inspector of Fertilisers.

FARM LABOR.

ACTION BY IMMIGRATION DEPARTMENT.

Owing to applications from farmers for farm laborers required by them for the coming harvest not having been received in time for arrangements to be made for the selection of and passages for men from the United Kingdom, the Government have appointed Mr. J. B. Tothill, a South Australian farmer, at present in India, to select from the ranks of time-expired soldiers in that country, men suitable for farm labor in South Australia. It is proposed that the men, who will be about 30 years of age, should be drawn from the cavalry and artillery regiments and from regiments recruited in the country districts of the United Kingdom, and it is expected that they will soon adapt themselves to farm work in this State. The fact that they are trained in discipline should compensate for their lack of experience in our conditions of farming. Mr. Tothill states in his reports that a number of excellent men are available. It is expected that the first batch will arrive here about the end of October, and farmers desirous of obtaining men should at once apply to the Immigration Department, as only a limited number will be encouraged to come to the State. A number of applications have already been received. Farmers who prefer to have agricultural laborers from the United Kingdom can be supplied with unassisted or nominated immigrants, of whom a number will arrive during the next month. Forms of application may be obtained from the Secretaries of local Agricultural Bureaus.

All that the farmer requiring a man is now asked to do is to advise the department of his requirements, stating the conditions of employment, and guaranteeing to pay the cost of transport of the laborer from Adelaide to his destination. The employé will be given to understand that he is to sign the usual agreement for such cost to be deducted from his wages, with the provision that the amount so deducted is to be paid to him in full if he remains for six months in the farmer's employ. The application form contains no guarantee of employment for a particular period, but the farmer is asked to say whether he can offer permanent employment to a suitable man. It is important for the new arrivals to obtain more than casual labor, and it is desirable that they should settle down in permanent employment until they are in a position to start on their own account.

IMMIGRATION OF LADS FROM THE UNITED KINGDOM.

Reference was made in the Governor's speech at the opening of Parliament to a proposed scheme for the introduction of lads from the United Kingdom. Briefly stated, the proposal is to introduce lads of from 15 to 19 years of age and place them with farmers, who will provide, in addition to food and clothing, a weekly wage and undertake to give the lads a training in farm work, so as to fit them to become settlers. It is believed that this scheme is superior in many respects to adult immigration. The lads would have nothing to unlearn, and would arrive at an age when they would be able to adapt themselves to South Australian conditions, and in course of time would constitute a body of young men from whom we would be able to draw many of our best settlers.

In the first place, the Government desire to ascertain whether there is a demand for lads on the farms, and, if there is, it is proposed, subject to further information being obtained, to proceed with the scheme. A number of those selected would be town lads who are engaged at present as telegraph messengers, porters, errand boys, shop and office cleaners, packers in factories, etc., and, with few exceptions, would not know anything of farm work; but care would be taken that only those physically strong, robust in health, willing, hardworking, and of good character were chosen. Not only would they be medically examined, but also as to their fitness for the work they were about to undertake. Preference would be given to lads in scouts or other brigades.

The Hon. the Commissioner of Crown Lands took advantage of Sir Robert Baden-Powell's recent visit to Adelaide to discuss with him the question of bringing lads trained at the Scouts' farm schools in England to South Australia under the proposed scheme. Sir Robert stated that these lads would be particularly suitable for farmers here, and would be very useful to farmers' wives, as they are trained to make themselves useful in housework. They are also taught discipline and self-reliance.

The boys, on arrival, would be treated as wards of the Immigration Department, and the Immigration Officer would be empowered to enter into agreements with the farmers on their behalf. Forms of application are being distributed, and the farmers will be asked to state thereon the conditions under which the lads will be employed. They would be expected to pay them a minimum wage, to be decided after full inquiry. The rates suggested were as follows, in addition to board, lodging, and clothing:—From 5s. to 7s. 6d. a week on engagement; from 7s. 6d. to 10s. a week after three months; from 10s. to 15s. a week for the second year, and the current rate of wages for the third year. It is suggested that the boys should be paid double rates during harvesting period.

An apprenticeship would be arranged for three years, so as to ensure the farmer the benefit of the training he had given the boy, and he would not

feel that, by taking extra trouble in teaching him, he would be likely to lose his services in the immediate future. It is further suggested that the agreement should provide that the sum of 1s. per week should be paid to the employé for pocket money and the balance paid by the farmer monthly to the Immigration Department upon trust, to be retained, firstly, in payment of the amount advanced by the department at the assisted rate for the employé's passage to and expenses incurred on arrival in South Australia ; and secondly, in trust to be paid to the employé on his attaining the age of 21 years, or sooner, at the discretion of the department. This scheme of compulsory saving is considered to be an excellent one, as it will not only train the boys in thrift but at the end of the apprenticeship each boy would have from £70 to £100 to his credit, which would put him on the road to become a share farmer, and he would, in many cases, be able to help his previous employer to develop his farm. It would be satisfactory to the farmer to have somebody he knows something of and who would farm according to the farmer's own methods.

On the form of application the farmer will be asked to state the accommodation that will be provided, and, as explained in the footnote, he will be asked to say whether the lad will live with the family, take his meals in the house, and sleep in a separate building, or live entirely with the men. It will be important for the department to have this information, as it will be a guide in placing the lads, enabling the youngest to be sent to situations where they would be allowed to live with the families. In this connection it might be mentioned that the farmers will be expected to, as far as possible, make the conditions homelike for the boys.

It is proposed that the apprenticeship agreement should contain a provision for a boy to be removed at a request of the employer should he be guilty of such misconduct as would lawfully justify a master in dismissing a servant. The Immigration Department would also be authorised to terminate the agreement without redress should the employer not abide by any of its terms or not treat the employé properly.

Farmers desirous of obtaining forms of application or further information with regard to the scheme should at once communicate with the Immigration Department. The first batch of lads cannot arrive before March or April next, but it is necessary for the department to know at an early date the number likely to be required, so that definite arrangements for their selection and passages may be made.

APPLE—CLEOPATRA.

FRUIT.

Size—Medium to large, fair samples averaging 3in. long by 2½ in. wide. *Shape*—Oblong to round, in cool damp districts tending to become more or less ribbed or flattened oblong. In hotter and drier situations the fruit may become rounded or widest in transverse section. *Color of skin*—Pale-green strewn all over with lighter spots surrounding in each instance pale-brown specks. Occasionally a faint reddish-brown blush is noticed on the exposed side. When ripened in store the skin changes to a clear pale golden color and becomes covered with a sticky exudation. *Eye*—Closed with short connivent erect segments set in a moderately shallow basin which is flattened or ribbed down the side. *Stamens*—Marginal in position on the tube, which is long, narrow funnel-shaped, leading so dangerously near to the carpellary cavities that the dividing tissues often burst and admit germs of mould into the fruit. *Stalk*—About three-quarters of an inch long, stout and clubbed at the extremity. It is inserted in a slightly compressed or ribbed basin of a pale yellowish-green color, the walls of which are sometimes faintly streaked with a lighter tone. *Flesh*—Pale creamy yellow, possessing a crisp tender texture, and mild, almost sweet juice, but not aromatic or vinous. *Seed cells*—Elliptical, abaxile.

TREE.

Habit—The young tree is an erect and vigorous grower, but owing to a tendency to bear its crops in bunches on the ends of laterals, by maturity it has assumed a globular head. The laterals are stout, smooth, and the bark of a reddish-brown color sprinkled with a few raised light dots. On the older limbs the bark becomes dull and dark-brown. The buds along these laterals

are virile, and if cut back those near the base grow freely. If left unpruned the terminal buds fruit first, and becoming depressed by the weight of the fruit those nearer the base break into growth, thus providing for future shortening. The leading shoots should be pruned fairly severely for several seasons to form a stiff base, but afterwards moderate topping alone is necessary. The dark-green smooth foliage and fruit are very subject to fusicladium injury, whilst the "bitter pit" is usually more prevalent in this variety than in any other popular kind grown here. The fruits are subject to malformations indicated in a crumpled eye end, popularly known as "bull nose," due mainly to only a partial fertilisation of the female organs being accomplished. It is a consistent and heavy cropper. *Climatic and soil conditions*—The climatic and soil conditions found most suitable are present in the drier portions of the fruit-growing areas of the State of South Australia, such as in the districts of Barossa, Clare, and Wirrabara, where it is the leading variety grown for export and home purposes. It blooms with Jonathan and Dunn's Seedling in early October, and is ready for shipment towards the end of March, lasting for local purposes until July and August. *Origin*—Somewhat obscure; the same apple is grown in Tasmania under the name of New York Pippin, which is not correct. The name Cleopatra was probably applied first in South Australia, where the fruit was formerly sold under the incorrect name of Pomeroy. There is much reason to believe the variety is of American origin, and possibly identical with an old Massachusetts apple called Salem. In the Government orchard at Mylor the last-named apple obtained from Leroy, of Angiers, France, appears to be identical with our Cleopatra.

POTATO SPRAYING.

TESTS AT MOUNT GAMBIER DURING SEASON 1911-12.

By G. QUINN and R. FOWLER.

These experiments were initiated by the Department with the object of trying to prove whether spraying would be of any benefit in checking the ravages of Irish blight, and incidentally any other fungus disease attacking potato plants, and whether it would pay farmers to adopt it as a general practice in this district. It was also deemed desirable to give a practical demonstration of a machine at work, and of the methods adopted in the mixing of various spraying compounds. The interest taken in this latter part of the experiment was hardly what it might have been, presumably owing to the fact that farmers were very busy at the time with the barley crops.

It was recognised by the Department that to convince farmers of any benefits to be derived from the spraying of potatoes it would be necessary to carry out the experiments in various parts of the district, so that they could personally visit the plots and see the results for themselves. With this object in view, plots were chosen representing various qualities of soil in different parts of the district, so that the tests would be as fair as possible.

The four plots chosen were in extensive fields, grown by Messrs. A. B. Sinclair, Buchanan Bros., F. Webster, and W. Hay; and our thanks are due to these gentlemen for the very willing assistance given at all times to carry out the experiments in the matter of providing horses and drivers to work the machine and cart it from place to place.

When it was first decided to carry out these tests, the Department decided to provide a motor spray pump. Recognising that perhaps the cost of a motor pump would prove prohibitive to most farmers it was, however, afterwards thought better to provide a spray pump that would probably be most used; so a Doncaster pump, made by Langwill Bros. & Davies, of Melbourne, was ordered. This pump is worked by horse power and costs somewhere about £35 to £37 10s. The Doncaster spraying machine is fitted with a vat to hold 80galls., the pump being operated by a chain working upon a large sprocket wheel attached to the main wheel and a smaller one upon a shaft from which power is transmitted to the pump rod. It is provided with five double sets of jets which are movable, and can be adjusted to suit either the width of the rows or height of the plants. It is also supplied with a fairly large air chamber, which ensures a steady and continuous pressure; but this was not provided with a stop cock, and we found in practice that when the nozzles

choked up—a trouble incidental to spraying—the pressure went down while relieving them, and the machine had to travel a chain or so before it started spraying again. This we had remedied locally, and it now works well. A patent agitator is also provided, worked by the pump action. This is a very essential part of the machine, as it is absolutely necessary for the spray compound to be kept thoroughly mixed. The machine is conveniently worked by one horse.

In each field an area of six acres was mapped out in whole acres and half-acres, the half-acre strips being left between each sprayed plot as checks, pegs being put at each end, so that when digging time came a correct record could be kept of the returns from each plot, and the benefit, if any, could be accurately arrived at.

THE SPRAY MIXTURES USED.

To make the experiments as useful as possible, we decided to use both the Bordeaux and Burgundy mixtures, and to spray two acres with each, using different strengths, one double the strength of the other. The strength of the formula generally used for Bordeaux is the 6.4.40-50, but 4.4.40, *e.g.*, 4lbs. bluestone, 4lbs. fresh lime to 40galls. water was adopted in these experiments. The Burgundy formula used was the 1.1 $\frac{1}{2}$.10, that is, 1lb. bluestone, 1 $\frac{1}{2}$ lbs. washing soda to 10galls. of water. This mixture becomes more expensive than the Bordeaux, but is easier to work through the spray pump, and is considered by some authorities to be more adhesive. The method of mixing was that usually adopted for both mixtures, and clearly described by Mr. McAlpine, Victorian Government Vegetable Pathologist, in his bulletin on Irish Blight.

As this is not a paper on spraying generally, details of that portion of the work are not entered upon; but we should like to say that it is not, in our opinion (within limits of course), so much the strength of the bluestone compounds used, but the method of mixing and the manner and time of its distribution over the plants which makes for the greatest success in checking the spread of fungus diseases. While it may be necessary that the spray should settle on the foliage in a fine mist and not in heavy drops that would probably run off, a strong pressure must be maintained to force it amongst the leaves. If the foliage is well covered and kept covered with only weak copper sprays, spores which fall on the leaves are likely to be killed as they germinate.

In our opinion the machine that will give the best results and prove the most economical, more especially in large fields, will prove to be the motor-driven pump.

The machine arrived on December 15th—three weeks or a month behind time; the potato plants were then really advanced enough for the second spraying, but fortunately the season was not a moist one, and the Irish blight had not made its appearance in the crops.

RESULTS.

The first plot treated was Mr. A. B. Sinclair's, on the 19th December, and the other plots were taken in succession. The weather at this time was not

all that could be desired, being windy and showery. Details and results are as follows:—

Mr. A. B. Sinclair's Plot—Sprayed December 19th and January 9th.

Plot No. 1.	28 rows—	Sprayed twice with 1.1 $\frac{1}{2}$.10 Burgundy gave.....	72 bags potatoes.
" 2.	13 "	Unsprayed, as a check.....	35 "
" 3.	26 "	Sprayed twice with 1.1 $\frac{1}{2}$.5 Burgundy gave	77 "
" 4.	13 "	Unsprayed	34 "
" 5.	26 "	Sprayed twice with 1.1.10 Bordeaux.....	70 "
" 6.	13 "	Unsprayed	37 "
" 7.	26 "	Sprayed twice with 1.1.5 Bordeaux	73 "
" 8.	13 "	Unsprayed	30 "

Total, 4 acres, sprayed, 292 bags; proportion large to small, 3 to 1 bags. 2 acres, unsprayed, 136 bags; proportion large to small, 2 to 1 bags. Apparent gain on 4 acres, 20 bags, or 5 bags per acre. Value at market rates, £1 13s. 4d.

Messrs. Buchanan Bros.' Plot—Sprayed December 21st and January 11th.

Plot No.			Large Potatoes.	Small Potatoes.	Total.
1.	32 rows—	Sprayed twice with Bordeaux, 1.1.10 ..	114 bags	31 bags	145 bags
" 2.	16 "	Unsprayed	62 "	10 "	72 "
" 3.	32 "	Sprayed twice with Bordeaux, 1.1.5 ..	110 "	24 "	134 "
" 4.	16 "	Unsprayed	60 "	12 "	72 "
" 5.	32 "	Sprayed twice with Burgundy, 1.1 $\frac{1}{2}$.10	113 "	23 "	136 "
" 6.	16 "	Unsprayed	50 "	11 "	61 "
" 7.	32 "	Sprayed twice with Burgundy, 1.1 $\frac{1}{2}$.5..	120 "	15 "	135 "
" 8.	16 "	Unsprayed	49 "	9 "	58 "

Total, 4 acres, sprayed, 550 bags; proportion large to small, 4.91 to 1 bag. 2 acres unsprayed, 263 bags; proportion large to small, 5.26 to 1 bag. Apparent gain on 4 acres, 24 bags, or 6 bags to the acre. Market value at digging time, 7s. per bag, £2 2s. per acre.

Mr. F. Webster's Plot—Sprayed December 23rd and January 17th.

Plot No.			Large Potatoes.	Small Potatoes.	Total.
1.	28 rows—	Sprayed twice with Bordeaux, 1.1.10..	94 bags	11 bags	105 bags
" 2.	14 "	Unsprayed	48 "	3 "	51 "
" 3.	28 "	Sprayed twice with Bordeaux, 1.1.5 ..	90 "	8 "	98 "
" 4.	14 "	Unsprayed	38 "	5 "	43 "
" 5.	28 "	Sprayed twice with Burgundy, 1.1 $\frac{1}{2}$.10	87 "	11 "	98 "
" 6.	14 "	Unsprayed	39 "	5 "	44 "
" 7.	28 "	Sprayed twice with Burgundy, 1.1 $\frac{1}{2}$.5	91 "	12 "	103 "
" 8.	14 "	Unsprayed	32 "	4 "	36 "

Total, 4 acres, sprayed, 404 bags; proportion large to small, 8.61 to 1. 2 acres, unsprayed, 174 bags; proportion large to small, 9.23 to 1. Apparent gain on 4 acres, 56 bags, or 14 bags per acre. Value at market rates, £4 18s. per acre.

Mr. W. Hay's Plot—Sprayed December 23rd and January 17th.

Plot No.			Large Potatoes.	Small Potatoes.	Total.
1.	26 rows—	Sprayed twice with Bordeaux, 1.1.10..	57 bags	19 bags	76 bags
" 2.	13 "	Unsprayed	26 "	12 "	38 "
" 3.	26 "	Sprayed twice with Bordeaux, 1.1.5 ..	64 "	18 "	82 "
" 4.	13 "	Unsprayed	23 "	9 "	32 "
" 5.	26 "	Sprayed twice with Burgundy, 1.1 $\frac{1}{2}$.10	67 "	18 "	85 "
" 6.	13 "	Unsprayed	32 "	10 "	42 "
" 7.	26 "	Sprayed twice with Burgundy, 1.1 $\frac{1}{2}$.5..	75 "	14 "	89 "
" 8.	13 "	Unsprayed	34 "	8 "	42 "

Total, 332 bags from 4 acres, sprayed; proportion large to small, 3.81 to 1. 154 bags from 2 acres, unsprayed; proportion large to small, 2.94 to 1. Apparent gain, 24 bags, or 6 bags to the acre. Market value, £2 2s. per acre.

The plot on Mr. Buchanan's farm was badly frosted late in the season, the tops being almost completely cut back while quite green, so that to a very large extent any benefit that would have resulted to the crop from the protective influence of the spraying was lost as the plants did not die off naturally.

COST OF SPRAYING.

The quantity of spraying material used per acre varies a little according to circumstances, but we found during these experiments that the amount per acre usually worked out at 80galls. We, however, consider 100galls. per acre, when the plants are well grown, would cover them more effectively. If we calculate the cost of materials for each spraying of 80galls. per acre, without taking into account the cost of applying it, the result is as follows:—For Bordeaux, 1.1.10, 8lbs. bluestone at 3½d. lb. or 30s. cwt., 2s. 4d.; 8lbs. lime, say 2d.; total, 2s. 6d. For Bordeaux, 1.1.5, double the above, 5s. For Burgundy mixture, 1.1½.10, 8lbs. bluestone at 3½d. lb. or 30s. cwt., 2s. 4d.; 14lbs. washing soda at 8s. cwt., 1s.; total, 3s. 4d.; double strength, 1.1½.5, 6s. 8d.

GENERAL CONCLUSIONS.

To indicate the rate at which spraying may be done with the machine, when in good order and spraying material ready, we started (in Mr. Hay's) at 1 o'clock p.m., and finished in four hours, having to walk over a quarter of a mile back to the water supply to fill up. The actual time taken to empty the machine and spray one acre was usually from 25 to 30 minutes, and about the same time to go backwards and forwards and fill up the vat. The only record put up was in Mr. Hay's at the last spraying, the time occupied over the four acres being three and a quarter hours. Like all other farm operations, a lot depends on whether the machine used keeps in good order; and spray pumps are just as liable to stick up as seed drills, harvesters, &c.

Analysing the figures, we find that there is very little difference between the full strength and half strength. In Messrs. Sinclair's and Hay's plots the strong solution gave the best results, but in Mr. Webster's it is just the opposite; so that it is doubtful if it will pay to use double strength. It was our intention to have sprayed a third time, but just when this should have been done we were in the middle of a severe heat wave, which did so much injury to the plants that it was deemed not worth while going on with it.

On the above basis the cost for spraying an acre of potatoes three times with ordinary Bordeaux mixture should not exceed 13s. 6d., made up of spraying materials, 7s. 6d., pay of driver and an assistant to mix the spray compound, use of horse, and general wear and tear, 6s.—total, 13s. 6d. Although the use of washing soda in lieu of lime would involve an outlay of 2s. 6d. per acre extra for the same work, we are disposed to believe the saving of time by its use, as against procuring, keeping, slaking, and straining the latter, combined with the more frequent losses of time and temper caused by stoppages due to the lodgment of grit from lime in the nozzles, would work out in favor of the use of the soda compound.

As the season proved extremely dry and most unfavorable for the development of the Irish blight, the main factor which we set out to investigate was not forthcoming. The indirect results obtained, which we believe may be attributed to the use of the copper compounds, were somewhat informative, the leaves, and more particularly the stems, remaining green considerably longer on the sprayed than on the unsprayed rows. It may not be unfair to assume that the increased proportion of tubers in the sprayed plots was due to this prolonged period of assimilation, apparently made possible by the presence of the copper compounds. In the light of recent European investigations it cannot be claimed that the assimilative powers of the sprayed plants had been increased beyond those of the unsprayed checks, but were simply prolonged. It is the intention of the Horticultural Section to repeat the tests upon similar lines during the coming season, but the spraying will be commenced at an earlier stage in the growth of the potato plants.

MARKETING APPLES AND PEARS.

Report by TRADE COMMISSIONER.

The Trade Commissioner (Major A. E. M. Norton) has forwarded the following report on the marketing of apples and pears in reply to various statements which have appeared in the Australian press in reference to the vast difference there seems to be between the prices Australian shippers receive for their fruit and those charged by the retailers throughout England:—

It has been so often stated by Australians returning to their native States from England that while Australian apples and pears are sold in Covent Garden and other markets at prices that are almost unpayable, they have noticed the same fruit being sold in baskets in Bond and Regent Streets at prices which work out at 2d. to 6d. for each apple and pear, and all through the London suburbs and in the provinces small sound Australian pears are selling at 3d. apiece, and Australian apples from 4d. to 6d. per pound, and in consequence there must be some huge profits for these retailers.

Taking last season, for instance, the inference is that fruit sold at about 7s. to 9s. a case in Covent Garden was eventually retailed in London at 2d. to 6d. each, and in the provinces at about 5d. per pound, thus showing a profit to the retailer of something like 7s. 6d. a case.

These statements are very misleading, and prove that the little knowledge gained by the persons interviewed is very dangerous to the wellbeing of the producers.

It has been my business for about six years to look after the South Australian producers' interests in England, and I may say that I have made exhaustive investigations in regard to the marketing of fruit, both wholesale and retail, throughout the United Kingdom and the Continent, and as a result of these investigations I have come to the conclusion that the retailer here gets precious little of the "gilt."

The statements are not explicit enough to mention the variety and quality of apples and pears seen ticketed up in Regent Street at 2d. or 6d apiece, neither do they state the varieties or condition of the apples that averaged comparatively such low prices in Covent Garden. They single out a few of the most expensive shops in London—shops which are patronised by the class of people who would just as soon pay 2s. as 2d. for an apple if it were something they fancied. The number of this class of shop can be counted on the fingers of one hand, and the quantity of fruit they could take for the whole of the season is infinitesimal compared with the general supply—a "mere drop in the sea." The apples one sees in the shops referred to are Cleopatras or Jonathans. On looking up the average price for these varieties for the last week in April I find it to be about 9s. 6d. per bushel. They take it for granted that a retailer is able to sell 40lbs. of apples out of every case, though if put down at 30lbs. he would be nearer the mark.

Since I came to England the first time I have seen hundreds of cases turned out, and I can assure you that, weighing them in bulk, the average is anything between 36lbs. and 38lbs. net. It is quite the exception for a case to weigh 40lbs. net. It will be remembered also that the retailers have to weigh out in single pounds, hence my reason for saying that 30lbs. will be nearer the mark than 40lbs. The reports also generally assume that every apple in every case will turn out sound and be fit to sell at 5d. per pound. This also is far from being correct. It is the exception rather than the rule for a retailer to get all the apples out of any one case fit to sell at full price. There are always some in every case that have to be sold at "cooking" prices. For instance, say a man buys "Cleos" at 9s. 6d. per case, by the time he allows for the actual weight he is able to get out of a case and the waste, the fruit will cost him more like 3½d. to 4d. per pound. It will accordingly be seen that the retailer after all does not get too much "gilt."

During the past season I have personally sold thousands of cases of Cleopatras and Jonathans, and the lowest price that I took for any that were sound was 8s. per case, and the average was well above 9s., and I do know that a large quantity were sold at 4d. per pound retail in order that the purchaser might keep "clear decks." Remarks in regard to the retail price of pears is still further evidence of lack of knowledge. Last season pears

that were in any way sound were realising 24s. per bundle at auction, or about 7d. per pound. My experience as a shipper, from when the industry commenced, and a seller this end for six years, has shown me that the reason for the alleged poor returns is because there is considerable fault both ends, and I consider it is not to the interest of the producers to lead them to believe that it is due entirely to methods of handling at this end or to the retailer. That the producer has suffered through having unnecessary charges piled up on him in London I am well aware, and on many occasions pointed out where the trouble lies, and also suggested remedies. Such remedies, however, the producers, I regret to say, have been slow to adopt. Co-operation on the part of the growers has been very strongly urged for some years past, and until the growers fully realise the importance of this movement I fail to see how they are to get the control which will enable them to regulate the selling this end, or improve the methods of grading and packing their end.

I am not losing sight of the fact that in South Australia there is a number of most careful packers whose fruit on arrival in England is a credit to themselves and the State. At the same time we cannot shut our eyes to the fact that the number of indifferent packers predominates. It is the very large quantity of badly graded and packed fruit that is an important factor when considering the causes for low prices. To a very large extent the benefit derived as a result of good packing is considerably discounted by the heavy supplies of poor quality and damaged fruit. I do not wish to again refer to the faults which unfortunately obtain, but I may mention an instance of defect which came under my notice this last season in regard to one parcel that was consigned to me. The specification indicated that in the shipment there was really fine fruit. In the circumstances I communicated with some of the best buyers in London, telling them that I expected some fruit of special quality by the incoming ship, and requested them to hold off buying elsewhere until they had seen these apples. An inspection of the fruit on arrival revealed something quite different from what was anticipated. All the cases were branded in bold letters "FINEST SELECTED," but the contents of the case could not have been considered even fair average quality, and the largest of the apples did not exceed 2½in., while they were all packed on the slack side. I am aware that the average of the fruit grown in South Australia during the past season was small, a defect for which the growers were not responsible; but the grievance this end was that growers or packers should try to make up with the stencil plate the deficiencies of nature.

Amongst the many great advantages to be gained by co-operation the following are two very important factors:—The number of marks would be reduced to a minimum; distribution this end could be controlled in such a way that at no one centre need there be an undue accumulation.

DISEASES OF FARM ANIMALS.

RINGBONE.

By F. MURRAY JONES, L.V.Sc., Assistant Veterinary Surgeon.

What is ringbone ? In what form does it occur and how does it affect our stock ? What remedial or preventive measures may be adopted ? The answer, briefly, to the foregoing questions in a simple and non-technical manner is the object of the following article.

Ringbone is a term given to an abnormal growth or deposit of bone upon the pasterns. These bones are two in number, and spoken of respectively as the upper, or long, and the lower, or short.

All breeds of horses are liable to ringbones, but heavy draught horses are especially liable, as their bones are more upright and shorter than those of the blood horse, and concussion is more violent as a consequence. The arrangement or anatomical construction of the horse's foot and leg is such as to minimise the chances of concussion and subsequent inflammation. In spite of this natural provision we must at the same time remember the artificial surroundings and the severity of his labors on modern macadamised roads, conditions oftentimes out of proportion with the most generous provisions made by nature.

Ringbone may occur on the front or hind pasterns ; it may be on the upper bone, when it is called " high ringbone," or on the lower just above the hoof, when it is denominated " low ringbone." Confusion must not be made with another condition known as sidebone, a subject which has been dealt with in a previous article.

It must be remembered that the growth of ringbone is from without and not from within the bone. This bony substance originates from a thin membrane, technically known as periosteum, which covers the bones. It is by concussion of this membrane by such causes as severe work on the hard roads, &c., which inflames and stimulates its function of producing bony material. This is really an excess of calcareous phosphatic matter, which becomes deposited around the bone. This is actually caused by a greater strain than the existing bone could endure. It is really a process destined to prevent a recurrence of the strain by providing against a like contingency.

A great many horses are naturally predisposed to the occurrence of ringbone ; that is to say, have inherited a natural weakness in the bones, to be followed by the presence of a ringbone under the most favored of conditions. This is generally found to be the case with soft spongy round-boned animals.

In the latter cases it is no uncommon experience to find other bone affections, such as spavin, splint, and other exostoses, as these are called, associated in the same animal, at once pointing to some constitutional weakness in the bone structures.

The effects on our equine stock are wider and more general than may at first be imagined. By no means is it an easy task to assemble at a short notice half a dozen of the hairy or heavy type of horse absolutely free of this trouble. Although many affected are able to work, yet it is an undeniable fact that their years of active usefulness are greatly curtailed by reason of its presence. This reduction in the animal's years of usefulness represents a fair sum of money to owners and workers of these expensive animals.

SYMPTOMS.

In an animal affected with ringbone certain peculiarities are shown in the gait or mode of progression. In the first place there is an alternating stilty action of the limbs. If this form of trouble should be present in the front feet it will be found that there is a strong tendency to move forward on the heels ; by so doing the animal is endeavoring to avail himself of the benefits of the frog pads in lessening the jarring or concussion. In the event of the trouble existing in the hind limbs, the tendency to move forward on the toes will be shown.

In the early stages of forming ringbone the lameness is generally continuous and acute. Later on, in the more chronic form, the lameness, although being present in a varying degree, is more of a mechanical than a painful character.

TREATMENT.

How can we remedy this condition ? Well, in the first place surgical and mechanical methods are beneficial only in a very small degree. In the case of incipient ringbone—that is one just forming—the best way is to spell the animal and apply wet packs to the part, or turn the animal out for a long rest in a suitable paddock. Blistering for cases of older standing has been recommended, but the results are not always gratifying.

From the shoeing standpoint something may be done to alleviate the lameness. In practice, the affixing of a bar shoe to feet has been found beneficial. In the case of the front feet draw the shoe out very thin at the heels. In the case of hind feet let the shoe be fairly thick at this part. Sometimes the interposing of patent rubber pads between the shoe and the feet has been beneficial by lessening concussion.

In spite of the foregoing advice we must not lose sight of the fundamental fact that horses affected with ringbone are suffering as the result of an hereditary taint. If we are serious in our desire to reduce our percentage of affections of this sort we must aim at the cause, and the cause in the past has been faulty selection; that is to say, breeding has been done in a great many cases from animals affected with hereditary ringbone. It should be the ideal of the horsebreeder to breed sound animals, and the only way to reach this ideal is to breed from sound stock. As a means towards that end owners of stud animals should avail themselves of the Government certificate awarded in accordance with the condition of soundness. The natural result will be an enhanced value of the service of the qualified animal to all intending breeders. By adopting a rigid adherence to the principle of breeding from only selected sound animals much will be done to mitigate the evil of our subject, and the shrinkage of that high percentage of hereditary bone troubles, only too rampant in horses of the present day.

POULTRY NOTES.

BY D. F. LAURIE, Poultry Expert and Lecturer.

OPERATIONS FOR OCTOBER.

THE ALL-ROUND BREEDS.

While the egg production branch of the poultry industry in this State is making very satisfactory progress there can be no other conclusion than that the table bird section requires reviving. The marvellous perfection attained by many prominent strains of Leghorns in the matter of egg production has led to false conclusions. It seems to be the general opinion that egg production is the only branch of the industry which pays, and that there is no money in table poultry. This mistaken view has been furthered by certain breeders of White Leghorns, who naturally seek to influence all the business they possibly can. Many others, who ought to know better, assume that a hen's value lies in the number of eggs she can lay. We are apt to compare the great strides egg production has made in this State with the reverse as existing in England and elsewhere. It must not be forgotten, however, that in other countries an equal and perhaps greater production per capita can be shown in the shape of market table poultry of very high quality. Owing to circumstances South Australia has a large exportable surplus of

eggs, and in that respect is unique among the States. She, however, is behind Victoria and New South Wales in the production of table poultry. A great many people ill-advisedly blame the introducers and breeders of the laying strains of Leghorns, also they blame the laying competitions. These conclusions are wrong. By all means let us develop egg production to the fullest extent. We have markets for unlimited quantities at most profitable prices. But we have also excellent markets, both local and export, for more prime table poultry than ever we are likely to produce.

The local market offers great encouragement, because consumption is increasing rapidly and retailers are often hard put to supply the demand. As regards really prime table chickens, they are practically unknown in Adelaide. Good fairly-fleshed young birds are often brought to market by the breeders, but really well and properly fattened chickens are unknown. Chickens turkeys, and ducklings are all sold by weight nowadays—in the trade at least—and it will pay to breed and fatten well the right class of birds.

The export market has been well exploited, and it has been amply proved that remunerative prices can be obtained for good quality. In fact, prices were obtained last year which were far in advance of what were ruling in Adelaide markets prior to the opening of the export trade. The growth of local demand, however, caused such enhanced prices that breeders neglected the export trade, which showed signs of falling off. Then again, for export, only prime well-fattened chickens are suitable. The local market buyers are by no means fastidious, and will pay for large fairly fat chickens without much regard to prime quality.

What breeds? This is a question frequently asked. There is a fair range of breeds from which to choose. Wyandottes are generally suitable for private families and for farm stock, as well as for the large breeder. Ordinary Wyandottes are good layers—the hens of some strains are better layers than others. The Wyandotte chickens fatten easily and make first-class table birds. Too much attention need not be paid to egg production. Birds of good type should be selected, and from 150 to 160 eggs per hen per annum should satisfy the breeder. This average will be for numbers and for a series of years. Orpingtons have always been popular, but, in many cases, the hens are indifferent layers and soon become over fat. At our laying competitions there are always to be seen Orpingtons, of good type and appearance, which lay satisfactorily. The black is the most popular variety, but those who breed the White Orpington are loud in its praise. In choosing specimens of either variety for commercial purposes, the over-large, heavily-feathered specimens should be discarded. You will find that even medium-sized hens will get very fat in their second and third year unless fed with proper care. At the same time there are many so-called laying strains of Orpingtons which are not only undersized, but, as proved in the laying competitions, the hens lay undersized eggs. These strains have been built up by a method of selec-

tion for number of eggs only, and little regard, if any, has been paid to other desirable points. Fowls bred upon faulty methods soon degenerate into worthless mongrels. The originator of the Orpingtons had in view various varieties of an all-round breed.

Plymouth Rocks are both handsome and useful, but are being bred more upon show than upon utility lines. A few years of careful breeding with proper regard for egg yield should place this breed upon a good footing. The chickens are excellent table birds, and the hens lay fine-sized brown-shelled eggs.

The Faverolles fowl has never become popular in this State, although the hens are fair layers of fine eggs. For table bird production the breed is in the front rank.

Langshans, if of the Croad type, are fine layers of dark-brown eggs, and the chickens are excellent for table, although rather slow growing.

Cross-breeding may be recommended, because of the use of Indian or Old English Game, or even low-set Malay male birds, mated with Wyandotte, Orpington, Plymouth Rock, Langshan, or Faverolles hens, very fine plump-breasted chickens can be produced. These command very high prices in Adelaide and are excellent for export.

This season is nearly over, but it is not yet too late to arrange for a few sittings of eggs with a view to further experience. Table bird breeding entails no more labor than is necessary in looking after laying hens kept for egg production. The need for advancing this section of the industry is great, and furthermore the profits are excellent, and the "crop" is a short one. All chickens can be grown, fattened, and sold by the end of five months at the latest.

Early hatching has proved profitable, and in this respect it is advisable to obtain some breeding stock so as to be in readiness in March or April. At the end of the breeding season it is generally possible to obtain good stock at a moderate outlay.

Warm weather will soon be experienced and the poultry will need proper protection from the heat of the sun. This may be provided by means of shelters made of brushwood, straw and wire netting, or by canvas (split wheat bags) on timber frames, or permanent structures may be made of galvanized iron. Many poultry keepers needlessly expose their poultry when they could be made comfortable at a trifling outlay.

INCREASED PRODUCTION.

There is room for unlimited production of eggs and table poultry of all sorts. The demand throughout the world is influencing the markets. The United States of America produced eggs and poultry last year valued at two hundred million pounds sterling, and still this was not enough, for they were forced to import to the value of £600,000. If every poultry breeder

in this State were to produce, during the next few years, 100 eggs and 100 table chickens for every one now produced there would be no glut ; no reduction in prices. What was not required for local and interstate demands would be absorbed for export. Many firms would embark on the export trade, and competition means better prices for good quality. What we need is production. Speaking of the American production, a well-known authority said, " and for the coming year it is safe to say that poultry will produce more money than ever. People are going to eat more eggs and more poultry than heretofore. They don't want so much of those packing house products whereof we have read so much during the past few months. Just pin this fact to the inside of your hat band, and figure to increase your flock of chickens as much as you can. You'll be bound to be a winner. If you have no chickens, and have a place to keep some, don't lose any time in making a start and utilise your spare time for what is sure to be some 'easy money' for several years to come." The advice is equally apropos of the circumstances ruling in Australia.

FORWARDING EGGS TO MARKET.

Poultry keepers who have not done so would be well advised to obtain, from the Produce Department, Adelaide, some modern egg boxes. These are fitted with cardboard partitions to hold 25doz. No chaff is needed, only the woodwool pads provided. The risk of breakages is very slight. These cases are far superior to ordinary kerosine cases. They cost 2s. 6d. each, and will last for years.

EGG-LAYING COMPETITIONS.

TWELVE MONTHS' TEST.

ROSEWORTHY.

[Started April 1st, 1912, and to terminate March 31st, 1913.]

Competitor.	Eggs Laid for Month ended September 30 h.	Total Eggs Laid from April 1st, 1912, to Sept. 30th, 1912.

NOTES ON EGG-LAYING COMPETITIONS.

ROSEWORTHY AND KYBYBOLITE POULTRY STATIONS.

Despite exceptional weather the progress made by all sections in each test during the month of September has been good. The appended reports of the Superintendents show that there is a considerable improvement over the results obtained during the same period last year. A most satisfactory point is to be noted in the excellent prices which have been paid for market eggs this season. The result will, no doubt, show a better margin of profits.

ROSEWORTHY.

The Superintendent reports—The general health of the birds is good. One hen in section 1 died during the month from crop trouble and one had to be killed, suffering from paralysis. The former hen has been replaced, but the latter has not. One hen in section 3 was afflicted with cyst, and one was badly strained; both have been killed at owner's request and birds have been replaced. I have to record five broodies in section 1, 58 in section 2, and one in section 3; total 64. The average maximum temperature for the month was 68.14°, and the highest reading 83.4°; the average minimum was 41.29°, the lowest reading being 29.7°. Wind, with more or less force, blew on 28 days—on 13 from the south-west, 10 from the north-west, four from the west, and on one day from the south. Rain fell on 17 days, the registration ranging from 1 to 63 points; total registration, 2.43in. The laying has maintained a fair average. The number of eggs laid by the 804 hens was 15,863 for the month, against 15,262 for August. The total number laid to date is 63,996. The feature in the month's work has been the consistent laying by the leading pen of birds, which laid 146; this was also the highest score for the month.

KYBYBOLITE.

The Superintendent reports—The general health of the birds has been good, though three deaths have occurred. These were all due to ovarian troubles. There has been a great improvement in laying on that of last month, and the average per pen is over 100 eggs better than for the same period of the last competition. The leading pen is still doing good work and is being closely followed by a second pen. The month's yield was as follows:—Section 1, 3,452; section 2, 759; total, 4,211. The early part of the month was very windy, wind coming from all quarters. Over 5in. of rain fell during the month, and about 4in. in one fall. The birds are still housed and so did not feel the effect of the wind and rain to the same extent they otherwise would have. The minimum temperature was 34° with a maximum of 74°. Wind was registered on all but four days.

1913-14 COMPETITIONS.

Copies of regulations and form of entry are now obtainable on application to the Poultry Expert, Adelaide. Farmers, pastoralists, fruit and vegetable growers have been allotted a special section.

BULLETIN ON THE POULTRY TICK.

The article which appeared in the *Journal* has been reprinted in bulletin form. Copies will be forwarded on receipt of stamp. This bulletin should be carefully studied by all poultry-breeders.

ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board of Agriculture was held on Wednesday, September 4th, there being present Messrs. A. M. Dawkins (Chairman), C. J. Valentine, C. J. Tuckwell, Geo. Jeffrey, G. F. Cleland, F. Coleman, Col. J. Rowell, Professors Lowrie and Perkins, and G. G. Nicholls (Secretary).

LICE ON SHEEP.

Mr. Valentine intimated that the committee appointed to go into the question of lice-infested sheep had had an interview with the Chief Inspector of Stock (Mr. T. H. Williams), who had gone to the Crystal Brook district with a view to make inquiries and to lecture before the Port Pirie Branch of the Bureau. There was ample power under existing legislation to compel owners of infested sheep to dip the animals. Without doubt, lice were very bad in a large number of flocks, and the parasites were spreading rapidly among the Merinos. The only way to effectually destroy the pest was to dip in a poisonous dip, and it was necessary that the first of the two dippings should be made within a month of shearing. Professor Perkins said that if it was done immediately after the sheep had been shorn with machines in many instances blood poisoning would occur. Mr. Jeffrey said that on the stations the dipping took place promptly after the shearing, the principal reason being that the sheep were then all together, and the operation could be performed with greater facility than otherwise would be the case.

CARRIAGE OF SHELLS AND LIME.

The Secretary reported that the Railways Commissioner had agreed to transport lime for agricultural purposes as well as sea shells in 6-ton lots at the same rate as superphosphate, viz., M class, less 20 per cent.

VETERINARY INSTRUCTION.

The Secretary reported that the veterinary classes were being commenced on that day, Riverton being the first one arranged for. The Director of Agriculture mentioned that until the end of October the only townships visited, besides that named, would be Blyth, Lyndoch, and Angaston. During the Roseworthy College vacation, however, four or five other places farther afield would be included. To begin with, only four lectures were being given at each place. Mr. Jeffrey expressed the opinion that the classes would be a great success. Mr. Coleman asked whether it would entirely remove any possibility of State-subsidised veterinary surgeons being stationed at different

centres. He considered that the eagerness with which the scheme of lectures had been accepted demonstrated that there was a great need for qualified veterinary surgeons in certain localities. The Saddleworth Branch, of which he was a member, was deeply interested in the matter. Mr. Cleland thought the stockowners should emulate the example of the vigneron and contribute to a fund which would enable them to secure the services of veterinary surgeons where they were most needed. Professor Lowrie said the policies concerned were those of two different Governments. The present scheme of veterinary lectures he put forward when he undertook the direction of the Agricultural Department, without any knowledge that any other scheme had been discussed or even contemplated. He realised that there was a great need for the farmers to be helped in such a way that they would know how to avoid diseases and to treat simple complaints when these occurred. A lot of stock were now lost through lack of a little elementary veterinary knowledge and by the administration of quack remedies. The purpose of the lectures was not to qualify those who attended them to become veterinary practitioners. It was well known that a long and arduous course of study was essential to enable a man to become a fully qualified veterinary surgeon, a course which was almost as expensive as that required to secure a medical degree.

Scattered Population.—A great difficulty in South Australia was that the population was so widely scattered that there were few districts which afforded an opportunity for a man to earn a good living practising as a veterinary surgeon. The appointment of State-subsidised veterinarians would be all very well for the stockowners in the immediate neighborhood, but what about the men 50 and more miles away? Further, was it likely, seeing that the veterinary surgeons appointed would probably want to do all in their power to build up big private practices, that they would give out the best of their knowledge and information in the form of lectures? Certainly not. If, as had been suggested, a subsidy of, say, £100, would be sufficient to ensure the services of a qualified practitioner, surely in a district like Strathalbyn there were 40 farmers who could subscribe £2 10s. each to make up the requisite amount. If the scheme was justified, let them put the money into it themselves. Personally, he did not think that they would get a good veterinary surgeon to look at it on those terms. In New Zealand, in some instances where veterinarians were privately subsidised, the salaries ranged up to something like £600 or £700 per annum. There, of course the population was more concentrated and 10 times as many head of stock were maintained on an equal area. To subsidise men on the scale outlined in the proposed scheme would bring to the State only young fledglings anxious to gain experience, and who would use the positions merely as stepping-stones to better things. It would be practicable, however, for the farmers who wished to have a veterinary settle among them to club together with

the object of obtaining the services of qualified men in the different districts, and such organizations would not be interfered with by the present scheme of lectures. Indeed, in all probability this would help considerably to awaken the farmers to a greater realisation of the advantage of having professional attention when their stock needed it. Mr. Jeffrey expressed his delight at the information given. He appreciated the force of the many points which had been emphasized. Mr. Coleman, while admitting the value of the veterinary classes, thought something might be done on the lines indicated by Mr. Cleland.

BERSEEM.

A summary of the results of experimental sowings of Berseem (Egyptian clover) seed made by various growers was presented by the Secretary, who stated that in most cases the seed had been put in without irrigation, and the plants, which had suffered very much from frost, had made little headway. There were one or two exceptions, however, and the most notable of these was that of Messrs. Dean Brothers, near Morgan. In this instance the seed was sown on March 25th on heavy loam, which had been ploughed and worked down just before seeding. The seed was rolled in and the ground was heavily irrigated immediately. Thence until June 3rd no rain fell, nor was the land irrigated. On that date, however, it was again irrigated, and rain occurred. After that the plot was in a swampy condition until August 20th, when the first cut, which stood 20in. high, was taken off. No manure was used. Professor Perkins mentioned that the plot at Roseworthy College (irrigated) had done well, and the third cut was now ready.

LIFE MEMBERS.

Mr. M. Manning (Carrieton) and Mr. M. Aitchison (Mundoora) were appointed life members of the Bureau in recognition of long and valuable service rendered to that institution and to the State.

FIVE NEW BRANCHES.

Approval was given to the formation of new Branches as shown—

Spalding.—Messrs. D. Wark, T. J. Preiss, J. Preiss, D. J. Campbell, S. Hennessy, M. Hennessy, D. J. McAskill, J. Pluckrose, W. Hacklin, E. E. Gill, P. A. Gill, M. McLeod, J. Shane, C. W. Smith, G. Thorn, S. N. Hallett, A. B. Jones, T. Walsh, D. A. Campbell.

Tintinara.—Messrs. J. E. Taylor, J. Wynes, R. J. Gully, C. P. Hodge, A. K. Wendt, J. Helling, A. Helling, R. K. Henderson, C. M. Ives, D. Bell, N. Bell, E. Northcott, G. Ives, — Stead, F. Stead, D. T. Kennedy, R. L. Scott, L. M. Scott, J. Donaldson, G. Bainger, — Bainger, M. F. Hodge.

North Booborowie.—Messrs. W. B. Ashby, A. V. Simpson, M. Canny, K. Phillips, F. L. Phillips, J. L. Farrelly, W. Banes, A. S. Toll, W. Toll, W. C. Catt, F. C. Catt, E. J. Morgan, W. E. Hannaford, E. J. Dunstan, J. W. Smart,

H. T. McQuillan, L. D. Clarke, T. Victory, W. C. Warner, W. Giles, C. J. Giles, G. E. Roberts, S. Mutton, J. Sullivan, W. F. McEvoy, P. McColive, T. H. Jeffery, G. E. Schaefer, F. C. M. Middleton, W. R. Birks, H. A. Mayfield, W. J. Cousins, H. A. Storr, M. Murphy, J. Murphy, P. Halls.

Glencoe.—Messrs. G. F. Ferguson, W. D. Mitchell, J. Dow, J. Halloway, W. Halloway, F. A. Telfer, M. D. Cameron, H. A. Cameron, W. Lehmann, P. S. Mitchell, W. Childs, jun., J. Riddoch, jun., A. Dow.

Mangalo.—Twelve members, whose names will appear in the next issue.

NEW MEMBERS.

The following gentlemen were approved as members of the Branches named :—Yallunda—W. Cabot, H. P. Cabot, J. Jones, S. L. Dix, A. Cabot, J. Winch, G. Gill, jun.; Hartley—F. Lehmann; Moonta—W. H. Bastian, R. C. Kitto, J. Andrewartha; Kalangadoo—J. Steele; Strathalbyn—E. Hall, M. G. Rankine; Keith—W. Graves, T. Packer, E. Aberlee, M. C. Redpath; Yongala Vale—J. Barker, G. Lloyd, C. Miller, D. Fowler, G. E. Edson, W. Campbell; Waikerie—C. Promnitz, W. Frahm, J. Jackmann, H. Aspinall; Gladstone—J. Slattery, R. Coe, F. Read; Riverton—Dr. R. McM. Glynn, O. H. Castine, D. Hannaford; Petina—W. Schultz, P. Barnes, A. Kenny, W. J. Lewis, A. J. Batt; Monarto South—H. E. Kuchel, J. Daly; Pinnaroo—L. Small; Warcowie—J. Marrow, G. Growden, E. Jarvis, F. Crossman, R. Bairstow; Port Broughton—D. Allchurch, E. Allchurch, H. H. Stephenson, G. H. Rantley, H. P. Whittaker; Nantawarra—R. D. Nicholls; Freeling—A. B. Anders; Blyth—J. B. Kirchner, F. A. Kirchner, A. B. Kirchner, M. G. Best, S. R. Neville, J. Williams, H. Neumann, H. A. Montgomery, J. Kostera, M. Vogt, A. Hamilton, D. Crawford, jun., J. F. Bishop; Pine Forest—H. Adams; Parilla Well—F. G. Webster, A. Webster, R. Noltenius; Arthurton—C. W. Bowden.

A USEFUL FIELD ROLLER.

THE AGRICULTURAL BUREAU.

TWENTY-FOURTH ANNUAL CONGRESS.

OPENED BY THE GOVERNOR.

The Twenty-fourth Annual Congress of the Agricultural Bureau was held at the Adelaide School of Mines and Industries on Monday, Tuesday, and Wednesday, September 9th, 10th, and 11th.

During the sittings the following delegates attended :—Amyton—J. J. Cormack, S. Thomas; Angaston—S. R. Smith, J. C. Jacob; Appila-Yarrowie—W. Francis, J. H. Bottrall; Arden Vale and Wyacca—P. A. Hannemann, R. Paynter; Arthurlton—J. Welch, W. R. Stephenson; Balaklava—T. A. Thomas; Belalie North—A. H. Warner, H. Waldhuter; Beetaloo Valley—P. Curtin, J. Ryan; Berri—W. R. Lewis; Blyth—A. L. McEwin, C. H. Zweck; Bute—W. H. Sharman, L. McCormack; Butler—D. B. Butler; Burra—F. G. Scholz, F. Duldig; Carrieton—M. Manning, J. Ormiston; Cherry Gardens—C. Ricks; Clare—F. W. H. Lee, D. Menzie; Clanfield—W. Queale, A. Richards; Clarendon—A. L. Morphet, A. Phelps; Coomeroo—E. Berryman, R. G. Polden; Coonalpyn—G. E. Venning, A. R. J. Gurner; Coorabie—H. V. Hobbs; Cradock—M. J. McAuley, A. Clarke; Crystal Brook—M. P. Pavy, W. W. Robinson; Davenport—A. Gosden, E. H. K. Messenger; Dawson—C. H. Meyers, H. L. Meyers; Dowlingville—G. Mason; Elbow Hill—J. Rehn, W. T. Cooper; Forster—J. G. Whitfield, J. Johns; Frances—S. Meehan, B. F. Feineler; Freeling—J. A. Kuhlmann, J. A. Mattiske, sen.; Gawler River—H. J. Dawkins, B. F. Hillier; Georgetown—S. Eyre, J. THE OPENING SESSION.

Congress was opened at 8 p.m. on September 9th by His Excellency the Governor (Sir Day Hori Bosanquet). Mr. A. M. Dawkins (Chairman of the Advisory Board of Agriculture) presided, and among others present were the Minister of Agriculture (Hon. T. Pascoe, M.L.C.), the Members and Secretary of the Advisory Board, and a large number of officers of the department, including the Director of Agriculture (Mr. Wm. Lowrie, M.A., B.Sc.), Professor Perkins (Principal Roseworthy College), and Professor Osborn (Vegetable Pathologist and Botanist).

The Chairman expressed the pleasure of those present at the presence of His Excellency, whom he asked to declare the Congress open.

ADDRESS BY THE GOVERNOR.

His Excellency said—"I esteem myself very highly honored by the invitation to open this Agricultural Bureau Congress of 1912, and I thank you all very heartily for the compliment which you have thus paid me. Let me first define my position. Mr. Dawkins, in the Chairman's speech last year said, 'The Agricultural Bureau is a means of bringing a body of men who are anxious to learn in touch and sympathy with those who are willing to teach.' Well, I am one of those who are anxious to learn, and, therefore, I will not detain you long with an opening speech, which might interfere with the opportunities of those who are willing to teach. At the same time I must congratulate the members of the Bureau upon the large numbers who are attending this Congress; there can be no doubt that the meeting together of those interested in the agricultural welfare of the country, to exchange ideas and experiences, to compare with each other the result of their labors, and to meet in friendly social intercourse is productive of immense benefit to themselves and to the people of the State. (Applause.) It is a mere truism to say that the wealth and prosperity of the State depends upon the result of the exertions of the agriculturist and pastoralist. The annual export value of the wheat and wool produced in South Australia is a measure not only of the well-being of the farmer and the pastoralist, not only of the prosperity of the railways, the tramways, the hotels, the racing clubs, the implement manufacturers, and motor car builders, but it is also a measure of the funds available for the prosecution of public works, and, therefore, it is a measure of the power of the Government to provide employment for those workmen who depend for their subsistence upon daily wages.

"A large proportion of the Government expenditure is justly based upon the construction of railways, by means of which greater wheat-bearing areas may be brought into cultivation, closer settlement may be largely extended, and the annual export of primary produce may be developed and expanded.

WHEAT PRODUCTION.

"Mr. D. J. Gordon, in an eloquent speech delivered at the Chamber of Manufactures, said, 'a determined effort should be made by South Australian farmers to force their grain production up to 30,000,000 bush.; it could be done. New South Wales had doubled its wheat production in ten years.' I cannot quote you all his speech, but everyone should read it. In conclusion he speaks of the evils of centralisation, and says, 'they should recognise, as Australians, the fundamental economic truth that it is the productive industries which really add to wealth, pay wages, and maintain a high standard of comfort.' These words should be written on the heart of every South

Australian. Gold mines are to be found in our wheat fields, and they are inexhaustible; but the price of wheat, it should always be remembered, is fixed by forces which exist outside the Commonwealth, and cannot be raised by any action of State or Commonwealth authority.

"I should only waste your time by attempting to describe the detailed progress of the Department of Agriculture. No doubt Professor Lowrie, your most able Director, will tell you all that is necessary; but I should like to mention the experimental farms at Loxton and Veitch's Well, because the experiments at those places and the lessons derived therefrom are of splendid advantage to the struggling agriculturist in his arduous battle with the difficulties of soil and climate elsewhere. At Loxton, standing in the wheat, which had been manured with 60lbs. to the acre of superphosphate, the ear reached well above my chin, and I have never seen finer or better filled out grain. At Veitch's Well the wheat was in splendid condition, and, although the experimental area was at that time unprotected by a vermin fence, the wheat showed little deterioration from the ravages of rabbits. In visiting Mount Gambier this year, I found that some of the farmers who had grumbled about the price of the land when they bought it, had gained more than double the fee simple in one year from potatoes or onions.

THE DAIRYING INDUSTRY.

"I would like to draw special attention to the dairying industry. Twenty-five years ago butter was made in a casual fashion in Australia for the local market; the position was changed as by magic by the coming of the cream separator and cold storage, and the dairying industry now yields the Commonwealth about £15,000,000 sterling per annum. The question is, does South Australia take her fair share in the participation of that profit. (Applause.) In the old days there was in Australia but one harvest. If the cereal crops failed the outlook was black. With the advent of the refrigerating appliances a brighter era began, and the dairying, frozen meat, and fruit trade arose, the planting of special grasses and fodder plants commenced, and great efforts were made, by importation of selected dairy cattle and crossbred sheep, to take the fullest advantage of the new trade which had arisen in butter and cheese and frozen meat. Does South Australia now take her fair proportion of the dairying trade? I have been at some trouble to get figures for 1911, and I make out that the yield of South Australian butter was valued at £424,000 sterling, of which £103,876 was exported, and that the value of cheese products was £37,000. The total production, therefore, of the dairying industry in South Australia, including the milk consumed as such, yielded during 1911. £631,000. The proportion of Australian butter exported is growing every year—in 1908 it was 55,700,000lbs. and in 1910 it was 87,928,000lbs. But taking the figures for South Australia only we find that the export of butter in 1910 was 10,717,486lbs. and in 1911 it was 9,691,666lbs., a decrease of

1,022,820lbs. The export of cheese in 1910 was 1,796,281lbs. and in 1911 it was 1,517,561lbs., or a decrease of 278,720lbs. on the figures for the previous year. Of course, those decreases were due to the dry season, and this year, I suppose, we must expect a further decrease. But that does not affect the question—Does South Australia take her fair share with the rest of the Commonwealth in the dairy trade? Dairying is a particular boon to the farmer, because it pays his cheque monthly. This prompt settlement must appeal with great force to men who are used to one crop a year, and at times not too sure of that. There is no fear of over production. (Applause.) The London market will take all the dairy produce you can send it at a considerably higher price than can be realised in Australia. For all those reasons I am giving for competition at the Show a cup for the champion dairy cow, and I earnestly urge farmers to consider the question of increasing the output of dairy produce in this State. (Applause.)

“ Before concluding I should like to say again that I consider this Bureau a most valuable institution ; it is a means of distributing and gaining information ; farmers, meeting together at the various Branches and discussing their experiences, learn from one another. There is also the human interest developed by meeting your friend at stated intervals, and cultivating your knowledge of his mind by conversation on subjects of intense mutual concern. I thank you once more for the compliment you have paid me.” (Applause.)

THE MINISTER'S SPEECH.

The Minister of Agriculture (Hon. T. Pascoe, M.L.C.), who was warmly applauded, said—

“ At this Congress we can fairly claim to have reached a higher level than has been the case hitherto. I am gratified to be able to say that the Bureau is stronger to-day than ever before. Interest has been sustained, not only in the general Congress at Adelaide, as is evidenced by the splendid attendance to-night, but in the district conferences, which are held under the auspices of the Branches situated at different parts of the State. The number of Branches is increasing, and has increased during the past year at the rate of about one per fortnight. The membership has now reached a total of about 3,000. These figures speak eloquently of the desire of the South Australian agriculturist to gain a greater knowledge of his occupation, and so become more expert as a tiller of the soil, and render better service to the State. It is very gratifying to notice the number of students who, on leaving the Roseworthy Agricultural College, connect themselves with a branch of the Bureau. Not only is this the case with the Agricultural College, but boys from Prince Alfred and St. Peter's Colleges who go on to the land are to be numbered amongst the Bureau membership. (Applause.) These young farmers have had educational advantages which the older men never received, and the result should surely be in the direction of better agricultural practices.

DISTRICT CONFERENCES.

"During the year district conferences have been held at Cherry Gardens, Kadina, Orreroo, Crystal Brook, Kingston, Cowell, and Lameroo. They were well attended, and it was a pleasure to be present and listen to the intelligent discussions on the problems connected with the cultivation of the soil. Various Branches in different parts of the State are conducting experimental plots for the purpose of ascertaining the most profitable wheat to grow, and the manurial requirements of the land.

KANGAROO ISLAND.

"Lately the department has laid out plots at Kangaroo Island, where there is a large area of ironstone country. It was found by the men who took up this land that it did not respond to their treatment. If success attends the trials of the Department of Agriculture on the Island the result will be to the benefit of the State as a whole. Shells from the Spit, on Kangaroo Island, have been applied to land deficient in lime, and the high percentage of that contained in the shells has made their application as an amendment to the land, a payable proposition. The shells are available to the general public at a price of about 8s. per ton at Port Adelaide. They should be well worth a trial in clay country. They are being used at Mount Compass and Kangaroo Island with good results. (Applause.)

VETERINARY LECTURES AND CLASSES.

"During the year a scheme of veterinary lectures and classes has been arranged. The department and myself have been surprised and gratified at the reception which the various Branches of the Bureau have given to this scheme. Out of 130 branches, 88 have agreed to form classes ranging from 20 to 40 members, in order that they may increase their knowledge regarding the common and simple ailments of stock, and thus, in such cases, be put in a position to treat them successfully. (Applause.)

ROSEWORTHY COLLEGE.

"Roseworthy College still holds its own as the foremost institution of its kind in Australia. (Applause.) Apart from its work as a college, its Principal (Professor Perkins) has been for a number of years conducting experiments in regard to wheat and fodders which will be of immense benefit to the farmers of South Australia. A man who, like Professor Perkins, conducts these experiments year after year, giving attention to the minutest detail, is, in my opinion, a benefactor of humanity. The value of his work will be better appreciated in a few years' time than it is to-day, as by then he will, as the outcome of continued experiments, be able to speak more confidently as to the results. Next year we hope to have a very much larger supply of seed wheat, true to type, for sale to farmers. The work of selection and raising

wheat true to type is proceeding at Parafield, Turretfield, Roseworthy, and in addition at Booborowie; and we hope to come much nearer than ever before to supplying the needs of agriculturists in different parts of the State. (Applause.)

NEW APPOINTMENTS.

“Two new appointments have recently been made, which we are hopeful will help us in our onward march towards perfection in agricultural science. Mr. J. Brown, B.Sc., has taken charge of Turretfield, where no doubt he will soon learn to apply the knowledge he undoubtedly possesses to local conditions. For a long time we have felt the need of someone to make investigations in regard to the various fungus diseases. The Agricultural Department recently combined with the University, with the result that Professor Osborn has been appointed Vegetable Pathologist and Botanist. His knowledge will be of service to the Agricultural Department in inquiring into diseases affecting our crops, and there is no doubt his work will prove of great interest and value to the State. We wish the two gentlemen I have mentioned every success in their new sphere of labor. (Applause.)

“The poultry industry is still in the hands of Mr. Laurie, an enthusiastic officer who spares no pains to make that industry a payable one in South Australia; and in this connection it is gratifying to know that the Roseworthy Poultry Station is the best of its kind south of the equator. In Mr. Quinn, the head of the Horticultural Department, we have also, as you all know, a most valuable officer. His Excellency evidently takes keen interest in the dairy industry. Although, perhaps, that industry has not progressed to the same extent in South Australia as it has in some of the other States, the reason is that, taking our State as a whole, the country is not so suitable as that in New South Wales, Victoria, and Queensland. Still, we are making progress, and I hope that by the settlement and full utilisation of reclaimed swamp lands along the valley of the Murray we will in the near future see a large increase in our dairy herds. Except there and in the South-East, South Australia does not possess the class of country necessary to enable the industry to progress to any great extent.

RAINFALL AND THE WHEAT YIELD.

“Lately I have been looking at the rainfall and other statistics, with the result that I have been struck by the progress which has been made in agriculture in South Australia. The figures are so interesting that I propose to have them printed in full. I think a study of them will convince you that as a result of the lessons which we have learned in past years we farmers in South Australia will not be so adversely influenced by a bad season occurring now and again as we were formerly; further, that a bad season will not have the same effect as formerly on our prosperity, and through us the prosperity of the State. (Applause.) The figures I wish to quote from are records taken

at the Observatory of the rainfall for each year from 1880 to 1911, together with the average wheat yield for each of those years. They are as follows :—

Year.	Rainfall at Adelaide.	Wheat Produced.	Average Yield per Acre.
	Inches.	Bush.	Bush.
1880.....	22·220	8,606,510	4·58
1881.....	18·192	8,087,032	4·34
1882.....	15·702	7,356,117	4·13
1883.....	26·761	14,649,230	7·56
1884.....	18·738	14,621,755	7·32
1885.....	15·887	5,161,000*	3·16*
1886.....	14·420	10,835,000*	5·50*
1887.....	25·701	19·012 000*	9·75*
1888.....	14·547	6,187,000*	3·85*
1889.....	30·874	14,577,358	7·91
1890.....	25·779	9,399,389	5·62
Average for 11 years....	20·802	10,772,035	5·79
1891.....	14·005	6,436,488	4·15
1892.....	21·625	9,240,108	6·08
1893.....	21·485	13,618,062*	7·86*
1894.....	20·782	7,781,223*	4·93*
1895.....	21·277	5,929,300*	4·20*
1896.....	15·173	2,804,493	1·66
1897.....	15·424	4,014,852	2·64

SUMMARY.

		Average Rainfall.	Average Yield per Acre.
		Inches.	Bush.
1880 to 1890	11 years	20·802	5·79
1891 to 1900	10 years	19·094	4·69
1901 to 1911	11 years	21·749	9·16

“ One of the first things I noticed in looking at those figures was that while the rainfall at the Observatory in 1911 was only 15·990in. the average

wheat yield for the State was 9·29bush., or higher than for any other year prior to 1905—when we were just beginning to learn how to properly treat our soils—with one exception, in 1887, when we had an average return of 9·75bush.; but that year, instead of having only a 15-in. rainfall, we had a rainfall of 25·70in. Last year then, though we had one of the lowest rainfalls on record, our wheat average was higher than—with one exception—that of any year prior to 1905. To still further illustrate the progress we have made in agriculture let me call your attention to the average returns for the years in which the rainfall approximated that of 1911. In 1882 the rainfall was 15·702in., and the average yield 4·13bush.; in 1885 the rainfall recorded was 15·887in., and the average return 3·16bush.; in 1896—that is the year all of us who come from the North well remember—the rainfall was 15·173in., and the average yield only 1·66bush.; in 1897, with a rainfall of 15·424in., the average was 2·64bush.; and in 1902, with a rainfall of 16·019in., the average yield was 3·64bush. per acre.

THE GROWING PERIOD.

“No doubt some of you will want to know what about the rainfall in the growing period of the years I have mentioned. Well, I will give you the rainfall during the growing period, from May to November, of those years, and in that respect I think last year will take a lot of beating, particularly in the North. At the Observatory the position was to some extent saved by the September rains, but these did not reach very far inland.

The figures are:—

Rainfall at Adelaide Observatory from May to November inclusive.

	May.	June.	July.	August.	September.	October.	November.	Total for growing period.

Average precipitation during above months for 11 years, 16·560in.

" Last year, as you will observe, in August 0·76 was registered, in September 3·80, in October (one of the vital months) 0·55, and in November 0·39. The total rainfall from May to November last year was only 11·880in. ; in 1882 it was 12·542in. ; 1885, nearly 13in. ; in 1897 it was 11·422in. ; and in 1902, 11·461, and yet with a rainfall of only 11in. during the growing period last year we raised the average yield for the State to 9·29bush. per acre. (Applause.) When you compare the figures, whatever credit you may give to artificial manures—and no doubt they deserve some credit—you must recognise that the more efficient working of the soil has made the artificial fertilisers useful and payable. (Applause.)

A FURTHER COMPARISON.

" During the 11 years, from 1880 to 1890, the State produced 118,492,391bush. of wheat. During the next 10 years, from 1891 to 1900, the production was 78,309,709bush. South Australia has produced during the past 11 years 185,575,150bush., and it is a noteworthy fact that the yield of the last 11 years very nearly comes up to that of the previous 21 years. The increase is not due so much to the larger area cropped as to the fact that we are farming much better. The average rainfall for the first term was 20·8in., and the average yield 5·79bush. The rainfall during the second term averaged 19in., and the yield 4·6bush. However, in the case of the past 11 years the average fall of rain was 21·75, but the yield was up to an average of 9·16bush. per acre. And despite some bad seasons, taking the last seven years, it will be found that the average yield was 11·18bush. to the acre. It is quite likely that we will, within the next 10 years, reach the 40 million mark for an average season in South Australia. I wish you every success, both in connection with the Conference and during the season now approaching. I trust that we shall all learn those lessons which will go toward making us better agriculturists." (Applause.)

THE CHAIRMAN.

The Chairman of the Advisory Board (Mr. A. M. Dawkins) said—

“ I am exceedingly pleased that His Excellency has seen fit to give his encouragement to the producing interests by opening the Congress. We have hardly realised the value of the part which the Bureau is playing in connection with the development of agricultural industries. In the sparsely settled districts it brings the neighbors together in a social manner, and many men have first learnt to express their views in public at the meetings of the Agricultural Bureau. The institution affords a means for the farmer to watch over his interests, and prevent the spread of noxious weeds and disease amongst stock, the qualities of which would perhaps be generally unknown but for the discussions taking place at the meetings. It affords a very excellent means for the expert to disseminate information amongst the tillers of the soil.

AGRICULTURAL EXPERTS.

“ The staff of the Agricultural Department is one of which we should be proud. The influence which has been exercised by Professor Lowrie on the agricultural practices of the State is hard to estimate. The increasing activity in the Agricultural Bureau shows that farmers are realising the value of scientific knowledge, and that they are anxious to secure information. The presence of the Bureau enables the experts to, as it were, feel the pulse of the farmer, and so ascertain the lessons which they desire to learn. With the experts on the one hand, and the members of the Branches on the other, an excellent combination of science and practical work is obtained. The man on the land is also learning of improved methods of cultivation and treatment of crops, and means of increasing the yields. Excellent work in this regard is being done by Professor Perkins at Roseworthy. During the last few years land values have been inflated; farmers must increase the production from the land, and see that it is worked to its best possible advantage, and Professor Perkins' investigations will go a long way to assist in finding the solution of the problem. I am very pleased indeed to know that the Minister has put the scheme for veterinary classes and lectures in operation, and I know that you are anxious to benefit through the scheme.

TRAINING AT ROSEWORTHY.

“ No one can listen to our veterinary experts giving a lecture without observing the eagerness of the farmers to gain information how to treat their stock. I have been surprised, while you manifest such a keen desire to learn from the Director of Agriculture, Professor Perkins, our veterinaries, Mr. Quinn, and other experts, all that they can teach you, that so few of you send your sons to Roseworthy College. If an occasional address from any of our experts is of so much value to you, how much more valuable to your sons would be the course of lectures on various subjects given at Roseworthy

College. If you personally feel the need of more knowledge on matters pertaining to the farm, is not there a need for it as regards your sons also? Increased knowledge concerning the work one is engaged in makes life better and more interesting, and I would strongly advise you, if you can possibly manage it, to send your sons to Roseworthy, where they will get a training which will fit them to become excellent farmers. The value of such a training is noticeable as regards the work of the Branches of the Bureau. I can, on reading the reports of the meetings of the Branches, pick out those which have as a member an old Roseworthy boy. I hope that this Congress will be most successful and that it will be a benefit to all." (Applause.)

Votes of thanks to His Excellency, the Minister, and the Chairman concluded the session.

TUESDAY, SEPTEMBER 10.

MORNING SESSION.

The Congress resumed its sittings on Tuesday morning. Mr. A. M. Dawkins (Chairman of the Advisory Board) presided over another large attendance.

THE BREEDING OF LAMBS FOR MARKET AND THE INCREASE OF FEED ON THE FARM.

Mr. Frank Phillips (Riverton Branch) read the following paper on "The Breeding of Lambs for Market and the Increase of Feed on the Farm":—

This question is so large and important to the South Australian farmer, and more especially to what we understand as inside country, that I shall only attempt to discuss it in view of the conditions pertaining in the district of Riverton, or similar country and climate. Let the farmer first decide on the class of sheep most suited for the work. I will not try to lay down any hard and fast rule, in favor of any particular breed, having only had experience with the large-framed station-bred Merino ewe, which is well adapted to our local conditions owing to its hardy constitution and power to withstand adverse weather. Cross this breed with the Shropshire ram, and we get a lamb which recovers more quickly from a check than the majority of other cross-breeds. In some cases this ram is found to be a very slow worker. During the winter he puts on a lot of condition, and when turned in with the flock, does not work at once. For the last three years I have always made it a practice to keep my rams in the sheep yards for about two weeks before they are required, and during that time supply them with very little feed, to work off some of the condition. When they are turned in with the flock they keep with the ewes better and do not wander away. In spite of this

precaution I have found them leaving the ewes. To make sure the percentage of lambs will be even and good, I have therefore erected a small yard in the paddock the sheep are grazing in, made of 3ft. pig-netting and a few iron posts, and by yarding the flock three or four nights a week for about two weeks I find the rams stay with the ewes and work better. Three years ago, by following this practice, from a flock of 224 ewes I tailed 208 lambs, none of them more than three or four weeks old; and three weeks later tailed 10 more, making a total of 218 lambs. I mention these figures to show that the Shropshire ram will work well if handled properly. I used three rams that season.

Some people consider that an even drop is harder to carry than a flock which is lambing for some time, and the lambs being sold off as they become fat; but as our season for fattening is not very long, I think the even drop is better to get the lambs off in one line. Should the local market not suit the farmer, he can make up a truckload and sell in the Adelaide market. Further, a farmer may, early in the season, intend to fatten the lambs himself, but later on he finds he is short of feed, and wants to sell. If the drop is nice and even the sale will generally be an easy and satisfactory one. Another point to add to the appearance of the flock and encourage the growth of the lambs, and which is not much practised in this district, is britching or crutching the ewes, *i.e.* shearing away the wool from below the tail and a little way down the hind legs. This keeps the hind quarters of the ewe clean in case of scouring, and reduces the risk of being troubled by the blowfly at lambing time. This work should be done not later than six weeks before lambing. Great care should be exercised in this work to avoid knocking and crushing the sheep in the yards. The right time for lambing is controlled by many conditions. I think the object of the lamb-breeder in this district should be to lamb at the latter end of April and early May, to get the lambs away in September and early October. Shear the ewes as soon as possible, to miss the grass seeds, and have the sheep ready to put on to the fallow land.

My remarks as to the time of lambing only refer to an average season when, in this district, we have green pickings in April, and fair feed in May, and other feed after that; but the lambing in a season like the past I would not attempt to discuss.

Sheep must be kept where wheat is grown, as they save a lot of work for the team by cleaning up the fallow lands. It is not wise to put woolly sheep on fallow, as that tends to reduce the value of the wool at once.

METHODS OF INCREASING THE FEED ON THE FARM.

To consider a season like the present, when a good paddock of feed is hard to find, we should look back a few months to, say, February. Most of the harvest work is then done, the horses are doing nothing, and the stock have had the best of the feed out of the stubble lands. In March we find

the farmer burning off most of the straw, and then he sits back and waits for early rains to bring up early feed for his stock and for his ewes to lamb on. During harvest there is always a certain amount of grain lost, not altogether due to the use of the harvester, but to the variety of wheats sown, which, when nearly ripe, shell out during a high wind. What becomes of this wheat? We notice it on the land soon after the straw is burnt off, and one naturally thinks there will be good feed for the stock, but nine times out of ten it does not come up to expectations. The fault lies chiefly with the farmer and not so much with lack of early seasons. Take an example—A farmer has 300 acres of stubble land which he intends to fallow up during the winter. He should cut straw on half the area with the binder, or break it down, rake it up clean, and stack in the paddock for shelter for the stock. While stacking sprinkle molasses mixed half and half with water over the straw. This makes a feed that horses and cattle will eat readily in the winter months. He should start the cultivator to work on the stubble land that has been cleaned of the straw to insure a better germination of weeds, &c. He can then let the other 150 acres stand with the straw, as a safeguard in a season like the present one. This would still help to keep his stock in condition until the rain came. After the first rains there are generally a few warm and drying days in which the straw can be burnt off fairly well, and knowing that he will soon have fair feed on the balance of the stubble land the farmer can then start fallowing, directly after seeding, the land which had the straw burnt off; and should this land become too hard to plough in a dry season he can turn his attention to that which was cultivated, and which should be easy to work because the early rains have not been allowed to run away. I have found that land treated in this way when ploughed in the winter always works beautifully. It does not turn up in lumps.

A good burn tends to keep the land free from weeds, &c., but why burn all the seeds every year? Why not work the fire stick in rotation, one half burnt off this year and the latter half worked as described? Red land is always clean after a burn, and very little feed comes with the early rains. Black and loose land cracks in the summer and allows the seeds of wheat and weeds to get out of the range of the fire, and thus we find more rubbish on looser lands. In this case I do not think it so necessary for the straw to be carted off, but burn and work as mentioned before.

Sowing crops for feed does not receive the attention the importance of the subject warrants in this district. If barley were sown on a portion of our stubble lands early in the year we could get a large amount of feed before the end of August, and then work the land as bare fallow. I have sown barley early on fallow and fed heavily, and then reaped a good crop. One year on 10 acres barley I fed 200 ewes with 180 lambs until the second week in September, and then reaped six large bags per acre. I brought the sheep on once every fortnight and fed for one week. In another season I fed 14

acres barley until September and reaped 18bush. per acre. In both instances this, together with the other feed on the farm, allowed me to fatten the lambs for market ; otherwise I should have had to sell them.

On another occasion I carried nine Shropshire rams from May 20th to the middle of October on one acre of barley, half an acre of natural grass, and with no water, and then they were too fat to work. Needless to say I did not look for a crop.

Instead of burning off barley or oaten straw it is wise to cut and stack it. If done directly after reaping and made into large stooks it will be sweeter and not so dry, also retaining a fair amount of color. This chaffed with hay and mixed with molasses makes a good feed for stock in a season like the present one.

Peas sown for feed is another good crop, and is coming more into use. There is no doubt that this crop helps to prevent takeall. Its feeding value is high, and the crop comes in for use when the other feeds on the farm are scarce. It can be fed in the green stage or when dry. I prefer to feed it dry. In one season I carried 400 odd sheep on 42 acres of peas during January, February, and March. There was a running creek in the paddock. I sold the sheep as fats.

Some people think that to erect fences for cropping small portions of the farm with fodder crops is too expensive. It is well-known that the smaller the paddocks on a farm the more stock it can carry ; but fencing is dear work at any time. My practice when putting 10 or 20 acres to barley or peas for feed is to run up a light fence made of 3ft. pig netting and iron posts, securing the netting to the posts with binder twine saved from the chaffcutter. It is quickly put up and removed to other parts of the farm, and if carefully handled the material will last a long time.

The figures I have mentioned have all been gained from my personal experience, and I think my neighbors will bear out the statements made in this paper, especially the latter portion. The whole question is one which must engage the attention of many farmers in the Lower North. We must make more use of stock on our farms, or I feel sure our crops must suffer in the long run.

THE DISCUSSION.

Mr. J. R. Beck (Hooper) said that Mr. Phillips had expressed the opinion that it was not wise to put woolly sheep on fallow. He had, a few weeks ago, read an article in which the writer said that he had got a higher price for the wool from sheep which had been run on the fallow.

Mr. S. Eyre (Georgetown) confirmed the remarks in the paper as to the damage done to the wool by putting sheep on fallow. His Branch had conducted a co-operative shearing depot, and had gone to the expense of engaging a classer for two years out of the three the depot was run. He could assure those present that the classer could tell at a glance whether the sheep had been

run on fallow or not. There was, however, a certain amount of advantage gained by keeping sheep on fallow, because if they got a less price for the wool they received benefit by the good the sheep did the fallow. He thought there was useful information contained in the paper.

Mr. Blesing (Port Germein) did not indorse the opinion of Mr. Eyre as to the deterioration of wool on sheep run on fallow. If they inquired closely they would find that the reason why the sheep took up dirt was because they were run on fallow directly after they were shorn, and they carried that dirt till the next shearing. During the last two years he had had his sheep running for about a month on fallow ground and they had kept the weeds from going to seed, and he got one penny per pound more for the wool than had his neighbors. Even if anyone got a little less there was so much more weight in the wool that it paid to let the sheep on fallow. (Laughter.) That was his experience, and he had been in the wool business for the last 30 or 40 years. He agreed with the writer of the paper as regarded the burning off of stubble. If people had kept their stubble this year they would not have lost half the stock they had.

Mr. D. McCallum (Willowie) said that sheep run on fallow grew more wool, although the wool was not worth so much per pound.

Mr. F. A. Wheaton (Redhill) asked if putting molasses and water on the straw would not tend to make it rot.

Mr. Phillips (Riverton) said it would not, providing common sense was used. The straw soon got dry, and in fact, if the molasses was put on one load when stacked it would be dry before the next load was ready.

Mr. H. J. Dawkins (Gawler River) had stacked straw when it was raining, but it had not deteriorated. He thought the paper very practical, and congratulated the writer. Mr. Phillips had said that he fed the rams well all the year round, and then about two weeks before he put them to the ewes shut them up in the yards to take off their fat. His practice had been somewhat the reverse. He kept the rams on poor feed until about three weeks before putting them with the ewes, and then put them on good feed so that they might get in good heart. He had always had a good percentage of lambs. Crutching was very essential. Stacking the straw was useful, and horses, even at this time of the year, would eat it readily. The question of humus came in, and Professor Lowrie would tell them that it was unwise to burn off except as a precaution against "takeall."

Mr. F. M. P. Pavy (Crystal Brook) thought the paper very good, especially the part dealing with breeding and feeding. It was useless to breed well unless they fed well, and the matter of increasing the feed on the farm was, therefore, very important.

Mr. A. J. McEwin (Blyth) said the only advantage he found from stacking straw was that it made a good shelter. He had stacked straw for a good many years, and last year was the only time he had found it of any use.

He never gave his horses straw, but stacked plenty of hay for them. He believed in stocking up to the full capacity. He had 3,000 acres. He cropped 1,000, had 1,000 in fallow, and carried 2,000 sheep. He had had a bit of a scare this year, but nevertheless had come out trumps. They should aim at increasing the feed on the farm. He had sown oats in stubble land—not on fallow—early in the year, and if they did so and kept the sheep off it for a few weeks they would have something to tide them over afterwards. The dry seasons were in a minority. Last season was a dry one and they had felt the pinch this year, but it was only a matter of a couple of months—April and May. If they stacked a small quantity of hay and sowed oats on the stubble, letting it have a little growth before putting the sheep on it, they would only have to feed them a short time. It was a good many years since Professor Lowrie had told them that if they increased the quantity of manure they applied to the land they would not only get a better return but increase its carrying capacity afterwards. He could confirm the Professor's statement. He had used 1cwt. of manure to the acre and people had thought he had gone cranky, but one season he had reaped an average of 33½ bush. As he had said before, straw was a fine thing for shelter for stock, but he did not believe in its feeding qualities. He had tried it 14 or 15 years ago and had thereby killed half a dozen horses, so had never tried it since.

Mr. F. Gasmier (Wilkawatt) said that the writer of the paper had referred to planting barley for feed. He thought it would be better to sow peas, as by doing so they would not only get the feed, but also enrich the soil. Peas were excellent fodder for both sheep and stock. He had found the stacking of straw very useful. He had seen cattle eat it heartily for hours. (A voice—"They did not die?") They had not.

Mr. T. Pengilley (Willunga) said he could testify as to the benefit of growing peas. He had on his farm about 6 acres, which for a number of years, though the land was cultivated well each year, would not grow wheat. Some three years ago he sowed it with peas and the following year it was put into crop, with the result that the crop came so heavy that it laid down. If it had stood up he would have had 4 tons to the acre from it.

The Director of Agriculture (Mr. W. Lowrie, M.A., B.Sc.) said he could confirm what Mr. Phillips had remarked in regard to the value of a pea crop, whether grown for grain or to be fed down, as means of lessening the risk of "takeall." He had received letters from men in the State to that effect. It was first brought under his notice by the experience of some farmers at Gumeracha. They grew wheat, and wheat only, until at last there came a time when their crops were very unsatisfactory. Then, however, they grew peas on their land, with the result that they afterwards could grow wheat as satisfactorily as they had in the early stages. The explanation there was not entirely that the growing of the peas reduced the risk of takeall, but the fact was that in those wetter districts the crops were

suffering from nitrogen starvation, and they were calling it takeall. The writer of the paper had done well to bring forward the subject, as it seemed to him that during the last few years the value of keeping sheep on the farm had not been fully appreciated. He felt sure that the farmers must keep more stock on their farms or otherwise the crops would suffer in the long run. (Applause.) The output of export lambs was not much better than it was 12 years ago, and that was to be deplored. There were some things in the paper which he did not altogether agree with. Mr. Phillips had advised crossing Merino ewes with Shropshire rams. It would certainly be more profitable to use half-bred than Merino ewes, and the crossing of the short-woolled ram with the Merino ewes had been found a mistake in all the States, as well as in New Zealand. If they had Merino ewes and mated them with short-woolled rams they might get a higher percentage of lambs than if they used other breeds of rams, but there would be a certain percentage of the lambs which would have to be held over, and these once checked were hard to get going again. His experience in New Zealand had satisfied him that the practice which obtained very largely amongst the farmers there of using long-woolled rams with Merinos was much to be preferred to the practice of using short-woolled rams. On the other hand if long-woolled rams were used he preferred the English Leicester. They could then start with large-framed Merino ewes, use English Leicester rams, and keep back the best of the ewe lambs for their flock. These half-bred ewes could then be put with either the Shropshire, Southdown, or Dorset Horn rams, with the result that the ensuing lambs would be nicer in the carcass, and the meat would be of a color that the English market was accustomed to. That unfavorable appearance of Austral'ian lamb in London was due to the large proportion of the Merino in it. If they could get more of the English breeds into the lambs they were exporting he was satisfied they would get better prices. He was sure that by adopting the course he had suggested they could get lambs as fat and of as good quality as they did at Canterbury. If farming land his aim would be to start with good large-framed Merino ewes and to use a long-woolled ram, and to keep the best of the ewe lambs for his flock. The Leicester-Merino ewes made good mothers, and he believed a man who looked after his sheep properly would get from them a percentage of 130 to 140 more easily than he could get a 90 percentage from Merinos. By following on the lines he had stated they would get ewes that would give them a good percentage, get lambs of a bigger weight at 5 or 6 months old, and the color of their meat would be more saleable in London. By using a Southdown ram with the half-bred ewes they would get lambs of a better carcass than if Shropshire rams were used, but they would take a fortnight longer to come to the same weight. All farmers, he contended, should keep a flock of sheep, and if they did so he urged them to proceed on the course he had outlined. On the

matter of saving straw he thought it well to husband the straw from time to time. He had not had any experience in using molasses and water, but would prefer adding salt to straw intended for feeding purposes. (Applause.) When feed was soft and watery the stock would benefit by having straw to eat.

Mr. Phillips, in reply, said he had written his paper from the point of view of the man who cropped half his land each year. The price of land in the Lower North was too high for them to afford to let it lie idle, and his idea was that they should get something out of it in the way of feed for cattle, sheep, or horses. He thanked members for the way in which they had discussed his paper. It was by setting down their experiences and discussing them that they benefited, and in that direction he could testify that the value of the Agricultural Bureau was highly appreciated by farmers. Personally, it had saved him hundreds of pounds.

THE MOST SUITABLE CLASS OF FARM HORSE FOR THE STATE.

Mr. W. P. Foulis (Willowlie) read the following paper on "The Most Suitable Class of Farm Horse for the State":—

In travelling through the State one is struck with the want of uniformity in our farm horses. There are only a few farms where a uniform type of high-class animal is kept. Clumsy, over-grown draughts are seen working alongside of lighter mongrels. A really good team is frequently spoiled by the inclusion of an overgrown or stunted mongrel.

In defining the most suitable class of horse for the State one must take into consideration all the conditions. In many of our far-northern districts, and in the loose mallee country, the work is comparatively light, whilst in some of our more southerly districts, where there is heavy clay, the work is sometimes on the heavy side. The climate of the whole State is a changeable one, and is subject to more or less droughty conditions. To meet these conditions a horse must be of a moderately heavy stamp, of a strong, robust constitution, and a good doer. One of the chief qualifications required in a farm horse is that he shall be a fast walker, otherwise he cannot be considered a suitable animal, even if in other respects he is all that could be desired.

Before dealing with any particular breed, I will state a few characteristics to be looked for, namely:—Compact build, round barrel well ribbed up, short back, good sloping shoulder, square quarters, wide and strong across the loins, broad deep chest, moderate to short leg with clean strong joints, plenty of well-developed strong-shapely muscle and moderate-size flat bone. I favor the medium draught. Not the class usually termed medium in the saleyard, for these are really light draughts, but something a little smaller than those used for heavy dray work. To give a better idea, let me quote some measurements taken from two horses of good type. The first animal is a

four-year-old compact filly, with square quarters, carrying medium quantity of hair, suitable for work on the lighter lands. The measurements are as follows :—Height, 15½ hands ; girth, 6ft. 5in. ; forearm, 23in. ; forecannon, 9in. The other is a matured horse, capable of doing the heaviest farm work required. His measurements are—Height, 16 hands ; girth, 6ft. 9in. ; forearm, 23in. ; cannon, 10in. I favor this class for many reasons. They are good travellers. In nine cases out of 10 anything heavier than this will be found in the body of a team. It is easier to breed them true to type, or to the standard I have set, than the heavier draught. The majority of heavy draughts are loosely built, and have a tendency to slab sides and long back. They are not such fast movers, their own weight often being a hindrance. They are not nearly so healthy, and cannot stand the strain of fast travelling so well. In a time of drought the medium draughts will be found more profitable, as they require less feed to keep them in condition.

Some farmers urge that it is more profitable to keep the very heavy stamp of mares, as a more saleable foal is reared. Up to three years of age the foal from the medium mare will hold its own ; after that the one from the heavier mare will probably have the advantage, but the price obtained for the foal is not the only consideration. After careful observation of brood mares I have come to the conclusion that the medium mare will travel faster than the heavy mare whilst carrying the foal. She will work nearer to the time of foaling, and will do more work whilst suckling the foal.

To breed foals for sale, mate the medium mares with a heavy stallion. A good foal is thus obtained, and one class of mare answers for all purposes.

In breeding for farm purposes, observe the characteristics I have mentioned, and if any are lacking in the mares see that they are strong points in the horse. To breed an ideal farm horse, both sire and dam should have good square quarters, round barrel, be well ribbed up, and have a fast, free action when moving. I consider there is not enough attention paid to the action of stud horses. Many farmers breed from their slow mares because they are the best in other respects, whilst they possess other mares that are almost as good, and are splendid walkers—from which a more serviceable foal may be obtained. In my opinion, in the show ring judges do not pay enough attention to the movements and action of draught stallions. The grooms should come into the ring mounted, and be made to trot their charges long distances at full trot. Stallions would not then come into the ring looking like whales, and we would have a better opportunity of judging their qualities.

To get a uniform class of horse we must breed a distinct breed, and not a cross.

Of the various known breeds I favor the Clydesdale. They are active, strong, are usually staunch, thrive well, are docile, and exceedingly

tractable and intelligent. The Clydesdale is an exceedingly handsome animal, and a good team of them is a possession to be proud of.

The great difficulty the average farmer has to face in breeding high-class stock is to get the service of a sound reliable stallion. He is not in the position to purchase one for himself. He has learned from bitter experience that it does not pay to patronise the travelling horse that is serving far too many mares. After having paid from £3 to £4 each for a few mares without getting any foals, he becomes tired of this, and purchases a stallion for himself. It is usually one of very inferior quality, but he finds that it pays him better than getting the services of a travelling horse.

It is rather hard to find a solution for the difficulty. If farmers could only agree, the scheme for horse-breeding societies submitted last year by Professor Lowrie would be a good one, and well worthy of at least a trial. With the help of the Government subsidy, this scheme would be a good thing for both the owner of the stallion and the breeder. In the event of the horse having a bad season some of the nomination fee could be refunded to those whose mares missed, and if the horse should sire a high percentage of foals, and the funds of the society become exhausted the deficiency could be made up from the subsidy fund. The great difficulty would be to get farmers to agree about the horse. Under this scheme there would be a guarantee that the horse would only serve a limited number of mares, and the services of a high-class horse could be obtained at a reasonable figure.

I think it would also be a good idea if, instead of each farmer keeping a stallion of his own, several co-operated and procured a really good one for their own use only. Arrangements could be agreed on for his keep. There are far too many stallions of an inferior class in the State; but under our present mode of working this seems unavoidable.

THE DISCUSSION.

Mr. D. Rowe (Northfield) said that he had been told that horses for heavy pulling required good hocks, as it was there the strain was felt.

Mr. E. J. Pearce (Whyte-Yarcowie) thought the present method of judging horses at shows was a very rough and ready one. It would be a great advantage if the stock were judged by points.

Mr. D. McCallum (Willowie) agreed with the writer of the paper that for farm purposes more work could be got out of a medium draught horse than could out of those great clumsy things with long hair on their legs, who, if working on wet ground carried large clods of it along with them. (Laughter).

Mr. J. R. Beck (Hooper) said his experience was that the medium draught did more work than the heavy draught. The question was how to make the

services of suitable stallions available to farmers. He thought the introduction of the premium system, as in vogue in New South Wales, would achieve that object.

Mr. J. F. McEachran, M.R.C.V.S. (Government Veterinary Surgeon) congratulated the writer of the paper. The main feature in connection with horse-breeding was uniformity of type, and, unfortunately, that did not prevail in South Australia. Before they could get uniformity of type, stud books would have to be instituted. Whether the stud books should be divided into two classes—Shires and Clydesdales—was a matter for members of the Bureau to consider. If Professor Lowrie's scheme were adopted they would get a better type of horses and improve horse-breeding generally.

Mr. McEwin (Blyth) hardly agreed that only on a few farms was there to be found a uniform type of horse. He thought the farmers of South Australia had a real good type of horse, but that it could be improved was beyond question. What horses in South Australia did the hardest work? It was the mongrel every time. He favored Professor Lowrie's scheme if it could be worked. During the last year or two, however, plenty of good stallions had been available. The writer of the paper advocated a medium draught, but the measurements he had given were those of a tip-top Clydesdale. If they measured the horses in their stables he questioned if one would be found of 7ft. girth. With the exception of show horses they would find few Clydesdale entires that would measure 7ft. in girth. The paper, however, was a thoughtful one, and he agreed with the writer in his main points.

REGISTRATION OF STALLIONS.

Mr. V. Koschade (Greenock) moved—"That this Congress recommends the Government to make provision for the compulsory registration and examination of all stallions permitted to travel for hire or service, and that a limited number only be permitted to travel in a specified area, according to the requirements of the district." If they could bring a class of horses into this State suitable, not only for farm work but also for export, it would be of great advantage. There was a great demand in India for horses of a good type. At present in some districts they had horses altogether too heavy for farm work.

Mr. W. Roenfeldt (Greenock) seconded the motion.

Mr. D. B. Butler (Butler) said a provision that only a limited number of stallions could travel a given area would press very hard on new districts like Eyre's Peninsula. His own district (Tumby Bay) had been travelled by a few first-class stallions, but the high fee prevented the farmers from utilising them. Now nearly every one of the farmers had his own stallion. He had bred horses all his life, and he had found that there was more in feeding than in

breeding. If a colt was fed well it would turn out a first-class horse. His experience was that the thoroughbred died first when any difficulties came along. At the same time he was glad to see that the first-class thoroughbred draught was being introduced. It would, however, be a serious mistake to do away with what they called the mongrel and compel people to pay a fee of £4 or £6 for the service of a first-class horse. (Applause.)

Mr. A. Gosden (Davenport) supported the motion. In his district they had to accept what stallions came along, and it was impossible to get a good team right through.

Mr. J. Smith (Hawker) asked if the resolution meant that no man could keep a stallion unless it was registered.

Mr. Koschade—"No; not unless they travel for a fee."

Mr. Smith said in that case he was entirely in accord with the motion. He thought in his district they had all the stallions that had been rejected. (Laughter.)

Mr. McCormack (Bute) said registration would practically be useless unless the veterinaries were given more power. At present if a horse was sound, no matter how much of a weed he was, he could pass the test and be registered, while on the other hand some of the finest horses in the State were rejected.

Mr. McCallum (Willowie) thought the resolution unworkable. If all the horses used for breeding purposes had to be examined by a veterinary, how much would it cost? A strange thing in his district was that horses condemned by the veterinaries were the best horses there.

Mr. McEachran said the examination of stallions had been instituted in Victoria in 1907, and they also included type and conformation. When the examinations were commenced here some stallions not of good type and conformation were passed, but now they not only rejected horses for unsoundness but also if they were not of good type and conformation. The matter of compulsory registration of stallions should receive careful attention. It was no use talking about uniformity of breed or type unless they could get rid of the many unsound stallions which travelled through various parts of South Australia. To achieve their object, however, there must be a uniform Licensing Bill throughout the Commonwealth. But before that could be brought about it would be necessary that the veterinary authorities in the different States should confer, so that they might come to a uniform decision. He failed to see how they could limit the number of horses travelling in any district, and suggested that the part of the resolution dealing with that matter should be excised, and that Congress should instead affirm the desirability of a uniform Licensing Bill being passed in all the States.

Mr. Koschade said the practice he advocated had been adopted in other places.

In answer to a question, Mr. McEachran stated that of 509 stallions examined, 115 had been rejected.

Mr. Beck (Hooper) suggested that the question should be referred to the Branches for their consideration.

Mr. McCormack (Bute) moved as an amendment—"That this Congress favors the compulsory registration of stallions, and also a uniform Stallion Licensing Bill throughout the Commonwealth, the registration not to take effect until 1915, and the matter to be referred to the Branches within four months."

The amendment was seconded, and carried by a large majority.

ONION-GROWING.

Mr. F. Simper (Mount Barker) read the following paper on "Onion-Growing":—

The onion is one of the oldest vegetables known. It is gaining favor year by year; therefore, it is necessary to increase the production to meet the demand. With a certain amount of knowledge and labor there are times when fair profits can be made by growing onions. In a district such as ours, where many of the holdings are small and the land expensive, it is necessary to combine agriculture with gardening by growing root crops. From the outset, I wish it to be strictly understood that these remarks on onion culture are intended only for this district or one of similar soil and climate. Should I describe the best methods for Mount Gambier and parts of Victoria, where the soil and climate are so suited for onion-growing over large areas with less expense than here, I am afraid that many would be misled. Onions can be profitably grown in this locality, and harvested at a time when the markets are bare of a good export variety, if sufficient care is taken to select patches of soil that are suitable for raising heavy crops of good quality. With a fair summer, onions from this neighborhood can be harvested in February or before the bulk of the Gambiers and Victorians are ready. The soil most suited for this plant is a loose, deep, dark-colored loam, which must be fairly well drained. Onions will grow almost anywhere in this district; but if top prices are desired they must be of quality. The results of onion culture on unsuitable land are too well known and far too risky to be recommended. If possible, select a patch of land that is open, giving all trees, hedges, &c., a fairly wide berth; and should it be at the foot of a hill, see that it is kept well drained in the winter; and also note that the ground must be kept free from weeds. Give the land a good dressing of yard manure at the end of the summer, or as soon as the former crop, whatever it may be, is taken off. After the early rain plough as deeply as possible, then harrow it well. If very lumpy put a soil grinder or roller over it; it can then be left until planting time, when, to improve the crop, an application of bone-super. at the rate of from 3cwts. to 5cwts. per acre should be applied. Onions have grown well on the same land several years following with the aid of manures; but a change of crop is necessary to

obtain the best results. I would recommend late garden peas or potatoes for a change. There are many varieties of onions to choose from. I have found the Brown Globe most suitable here, as it comes to maturity between the early sorts, which will not keep long, and the late kinds that are rather delicate for our climate. Select the best bulbs from the last crop, or the best that can be purchased, true to name. If they are cross-bred, make sure that it has not been with an early sort, or a great deal of trouble will be experienced at harvest time. About June plant these bulbs in rows, leaving a space of about 3ft. between every two rows, there will then be little trouble in gathering the seed heads. Promptness is required in gathering the seed when ready, as if left to get over-ripe much may be lost in handling. The heads should be cut off when about one-half of the seed is showing, and placed into large calico bags, so that it may be spread out thinly in the sun. When dry, thresh it out and put it through the winnower. Take note that the onion seed loses its vitality very quickly, and should not be sown after two years old. After ploughing or digging a piece of loose dark soil, burn leaves and bark of trees on top of same, so that the ashes can be raked in before sowing the seed. This burning will force the growth of the plants, and will also help to prevent weeds from growing. Sow the seed in April in drills about an inch deep. If water is laid on set the sprinklers going, and the young plants will show up in about three weeks. However, there will usually be sufficient rain to start the seed. Keep the seedbed well hoed, and by about the month of September, or when the plants are about 6in. high, transplant them in rows 7in. apart, putting the plants 4in. apart. Three rows may be set on two plough furrows 10½in. wide. When the planting is done after the plough, a line will not be required, and much of the stooping will be obviated by walking along the open furrow whilst planting. Do not pull the plants when wet. Trim their tops and roots a little, so that they may be the easier handled. The former leaves usually die off; but after a shower of rain they will take fresh root, and the hoe will need to be kept going to keep down weeds and the top soil loose. Some growers do not practise transplanting, and prefer to either drill in the seed or sow it broadcast at the end of winter, and when the plants are about 3in. high, thin out for a crop. The former plan, although the work of planting takes much time, is the surer and better one in this district. A good crop of onions should not be made up with a lot of "stiff necks." Good seed, with thorough cultivation on suitable land, will produce even-sized, solid bulbs. When the tops have fallen over they should be pulled and placed in rows, taking care to cover the bulbs with the tops, to prevent the sun from scorching them. When dry, the tops and roots may be pulled or cut off, and the onions graded and bagged ready for market. The gunnybag has been used in the past, but the present-sized cornsack now in use is suitable. Use only new bags for export, and brand the bags well. In dry seasons the crop may be doubled by

irrigation, the use of sprinklers being the best method. Diseases of this plant here are almost unknown ; and, unlike potatoes, the onion is not hurt by the severe frosts. The chief trouble is with the lucerne flea, which attacks the young plants in the seedbed. A remedy for this is a spray of strong tobacco-water. Slugs also decrease the crop in wet seasons. Dusting with lime is recommended ; but the hoe will help to eradicate the pest. Onion growers, who do not make big profits, will not be able to say they have had no work. In conclusion, I would like to say it is necessary for producers to co-operate more in disposing of their goods, not with the idea of skinning the consumer, or even the middle man, but to find other markets that are wanting. Although Australia has been abundantly supplied with onions at times, on other occasions it has been necessary to import from New Zealand, Italy, and South America ; therefore, when our markets are overstocked we should try South Africa and other countries.

VARIOUS OPINIONS.

Mr. C. Ricks (Cherry Gardens) indorsed the remarks made by the writer of the paper. It had been represented that a member of the Mount Barker Branch had kept onions for 18 months, and he desired an explanation of how this had been done.

Mr. Simper said that the onion referred to was of the Brown Spanish variety. As a general rule onions would not keep for such a long period, but in this particular case the vegetable had certainly kept for that period ; in all probability it had been stored in a warm, dry atmosphere.

Mr. J. Mitchell (Lyndoch) had been growing onions for a number of years. His experience had tended to prove that the bulb increased in size more when the top had fallen over. The keeping quality depended very largely on the variety. The greatest difficulty was to secure a remunerative price for the crop. This year the prices ruling were good, but in all probability next year there will be a much lower market.

Mr. Simper said it was necessary for the South Australian producer to look to other parts in order to find a market for this crop. During the present season he had sold consignments to West Australian buyers, and there was a probability that South Africa would purchase. Brown Globe was a payable variety. He had found that when good seed was sown, and the land was well cultivated, the tops would turn over of their own accord.

Mr. W. J. Dale (Northfield) expressed the view that the growth of onions and potatoes should receive more attention from farmers generally. He had successfully grown a crop this year, but would like to know the best quantity of stable manure to be applied to land for onion-growing.

Mr. Simper was of the opinion that a dressing about 2in. thick was most suitable. He would, however, recommend growers to experiment with different manures.

AFTERNOON SESSION.

Mr. A. M. Dawkins presided over a large attendance of delegates.

SELLING CATTLE BY LIVE WEIGHT.

Mr. Brown (Port Elliot) moved—"That this Congress is of opinion that fat cattle should be sold by live weight, and requests the Advisory Board to take action with a view to having the system introduced." He stated that his Branch considered that it was only fair to the cattlebreeder that the exact weight of the beast should determine the price to be paid. Guessing competitions held at various shows had proved that both farmers and butchers frequently guessed very wide of the mark when estimating the weight of a beast. The butcher did not guess the weight of his beef when retailing it, but very properly took care that the customer paid for the exact weight received. The cattle of South Australia as a rule were not so wild that they could not be weighed with the proper plant. There was very often no competition between local butchers, and the seller had to take what was offered. If the new system were introduced the beast could be sold at per 100lbs.

Mr. J. Morgan (Narrung) seconded the motion.

Mr. McCormack (Bute) said the question was whether they would get any more for their cattle after having gone to the additional expense of erecting weighbridges. Personally, he did not think they would. Proper weighbridges would have to be provided and fixed at the saleyards, and he could not see that any benefit would be derived.

Mr. A. F. Noll (Quorn) was of opinion that the adoption of the proposed system would entail considerable expense. It was not so much weight as quality that told.

Mr. J. Stone (Meadows) failed to see that any advantage would be gained if the motion were carried into effect. He presumed that it was intended only that fat cattle should be weighed at country saleyards, and as a rule there were not many fat cattle at those yards. Who should bear the expense of erecting the weighbridges?

Mr. S. Ockley (Penola) said that grain was sold at so much per bushel, and he failed to see why cattle should not be sold at per pound. There could be no fairer method. If the system was put in force in the metropolitan area the expense in proportion to the population would be very small.

Mr. Beck (Hooper) understood that the practice of selling by live weight had been in force in Glasgow for the last 40 years, and that should be pretty good proof that it was not against the seller. If a butcher made a mistake under the present system they might feel fairly sure that it was in his own favor. He did not think the expense worthy of consideration, especially as sellers were now losing more than it would cost to instal weighbridges at the large yards.

Mr. J. Stanton (Hartley) thought the motion should be amended to embrace all classes of stock.

Mr. Brown (Port Elliot) in reply, said he thought it would be better at first to confine the principle to one kind of stock. Even if the motion were adopted there would be no compulsion on those who wished to rely on their own judgment to put their cattle on the weighbridge.

The resolution was carried on a show of hands by a small majority.

THE ADVANTAGES OF ASSOCIATING WHEAT WITH SIX-ROW BARLEY ON SOME OF OUR LOWER NORTH FARMS.

Professor A. J. Perkins (Principal Roseworthy Agricultural College) contributed the following paper on "The Advantages of Associating Wheat with Six-row Barley on some of our Lower North Farms":—

THE OVERWHELMING PREPONDERANCE OF WHEAT IN SOUTH AUSTRALIAN FARMING.

Whilst we are all tolerably familiar with the fact that South Australian farming is confined mainly to the growing of wheat, few perhaps, realise how completely this useful cereal has monopolised all our available arable land. Hence I have thought it well to preface my advocacy of the modest claims of another type of crop with statistical data indicating what was the general disposal of arable land in South Australia in 1910. This information has been summarised below in Table I.

TABLE I.—*Showing General Disposal of Arable Land in South Australia in 1910.*

Crops.	Areas.		Percentage of Total Areas. %
	Acres.	Acres.	
Wheat—			
For grain	2,104,717		
For hay	336,439		
Bare fallow	1,263,243		
		3,704,399	89.44
Oats—			
For grain	77,674		
For hay	96,062		
Bare fallow	89,908		
		263,644	6.37
Malting barley	23,245		
Bare fallow	7,373		
		30,617	0.74
Sown grasses	—	26,416	0.64
Vineyards	—	22,952	0.55
Orchards	—	22,410	0.54
Green forage	—	20,728	0.50
Cape barley	11,228		
Bare fallow	5,810		
		17,038	0.41
Other hay and bare fallow	—	10,585	0.26
Pease	—	9,629	0.23
Potatoes	—	7,812	0.19
Market gardens	—	2,818	0.06
All other crops	—	2,944	0.07
Total cultivated area in 1910	—	4,141,992	100.00

We see, therefore, that close on 90 per cent. of a total cultivated area exceeding 4,000,000 acres in extent was directly absorbed in 1910 in the growing of wheat in one form or another; that oats absorbed between 6 per cent. and 7 per cent. of the same area, and that no more than 3 per cent. to 4 per cent. of this area was left available for all other forms of agricultural enterprise.

I am not here to argue that we grow too much wheat, nor even that we are unreasonably capricious in our ostentatious neglect of other types of crops. So long as the average net returns from wheat show good interest on the capital value of land there is no crop more congenially adapted to the climatic and economic conditions that form our agricultural environment. The capital value of land, however, is a variable quantity, not exclusively under the influence of existing farming average net returns. Within quite recent years have we not seen it sent up with a rush by a gradually expanding population, by improved methods of cultivation, and by a run of good seasons perhaps, too? And farms have exchanged hands at prices that would have staggered us some short while back. High prices in land, however, present disadvantages which soon make themselves felt, and as might have been expected, graziers were the first to feel the brunt of them. In this connection the pressure of economic conditions is more effective than that of legislative enactments. When a man comes to realise that money in the bank, or in gilt-edge securities, will return him both a higher and more certain income than grazing he sells his land to those who can turn it to better advantage and invests his capital elsewhere. The sum, on the other hand, which the farmer can afford to pay for his arable land is strictly limited by the average net returns of his crops; and here, it is to be feared, if wheat-growing alone is to be depended upon, that many a recent purchase has gone perilously close to the margin of safety. With wheat as the only saleable crop raised, or farming reduced to its simplest expression, the determination of average net returns has a beguiling appearance of simplicity. Nevertheless, where management is chiefly concerned, so much depends on the personal factor that no one individual can hope to put forward estimates likely to meet with general acceptance. And if, with a view to strengthening my case, I am about to make the attempt, it is with open eyes and with full consciousness of my own shortcomings in this unaccustomed role.

THE AVERAGE NET RETURNS FROM WHEAT.

I take it that average net returns are bound up with three factors, viz.—(1) Average yields; (2) average prices; and (3) cost of production. The first factor, albeit varying from district to district and from farm to farm, admits of comparatively easy determination. Over the past 10 years the mean wheat yield of the State has been represented by 9bush. 13lbs., with extremes of 3bush. 38lbs. in 1902 and 13bush. 15lbs. in 1909. The State

average covers too wide an area for my purpose ; I shall therefore narrow the field to the Lower North, in which for the present I am mainly concerned. Between 1902 and 1911 the Lower North wheat average was represented by 12bush. 14lbs., with extremes of 6bush. 5lbs. in 1902 and 16bush. 27lbs. in 1909. These averages, it is true, include farming practices both good and indifferent ; ventures both lucky and unlucky ; and, in the circumstances, if we take 16bush. as a normal and possible average we shall not have understated the case.

In the matter of prices, too, we continue on tolerably safe ground. I find that over the past 10 years the export value of wheat has averaged on the Melbourne market slightly over 3s. 4d. a bushel. This is not, of course, the price realised by the inland farmer ; and in South Australia we have honorable understandings to be taken into consideration too. Hence if, for the sake of argument, I adopt 3s. 6d. a bushel as an average price I shall not be accused of understating the case. Sixteen bushels an acre at 3s. 6d. represent, therefore, two years' gross revenue from arable land, or £2 16s. an acre.

What, on the other hand, is in present circumstances the average cost of production of wheat ? And here I know that I am treading on thin ice. I have seen the cost of production set down as low as 15s. an acre and as high as 45s. and 50s. Unquestionably the personal equation very largely dominates the situation. Nevertheless—merely as an expression of personal opinion—I do not think, if everything be taken into consideration, that the cost of production of wheat can be put down at much less than 40s. an acre. This leaves us with 16s. an acre to cover both two years' net profit and two years' interest on capital value of land or rent. An average net return of this kind, in my view, limits the *maximum* value of good arable land in existing conditions of farming to £6 or £7 an acre ; and we all know that within recent years these figures have frequently been exceeded, and at times very considerably so.

THE POSSIBILITY OF MATERIAL INCREASE IN THE AVERAGE YIELDS OF WHEAT.

It may be urged that in the course of time the average yields of wheat will tend to increase still further in response to still further general cultural improvements ; that what we have seen accomplished within our own times will be repeated in the future ; and, within certain limits, this is no doubt possible. It is as well to recollect, however, that increased average yields do not necessarily carry with them a corresponding increase in average net returns. They are generally acquired at the cost of heavier expenditure of capital ; and if they contribute towards swelling the public revenues they do not necessarily have a corresponding influence on the income of the individual chiefly concerned. Independently, however, of their relative profitableness there are definite limits beyond which average yields cannot

be expected to rise; and these limits are determined mainly by climatic factors over which we can have no control. If we scan the average yields of the principal wheat-growing countries of the world we shall see that the highest yields are recorded for countries placed within the colder and moister portions of the Temperate Zones—countries such as Great Britain, New Zealand, Belgium, Germany, &c. Here in Australia we belong, on the whole, to the hottest and driest portions of the Temperate Zones, if indeed we do not, in our northerly wheat-growing areas, encroach somewhat on the Torrid Zone.

TABLE II.—*Showing Recent Average Yields of the Principal Wheat-Growing Countries of the World.*

Country.	Year.	Area Under Wheat. Acres.	Average Yield per Acre. Bush. lbs.
Belgium	1909	395,244	39 13
Great Britain	1909	1,866,960	33 51
Germany	1909	4,523,311	30 30
New Zealand	1910	322,201	25 44
Canada	1909	7,751,921	21 31
France	1909	16,290,000	21 11
Japan	1909	1,107,540	20 8
Austria	1909	2,957,496	19 16
Italy	1909	11,629,375	16 20
Spain	1909	9,342,700	15 25
United States	1909	46,717,553	15 18
Hungary	1909	8,758,490	14 22
Servia	1909	921,006	14 20
Roumania	1909	4,172,756	13 11
Australia	1910	7,373,017	12 54
Russia	1909	48,644,800	12 28
Caucasia	1909	8,388,054	12 19
India	1910	32,793,638	10 53
Argentine Republic	1909	14,563,420	10 43
Siberia	1909	8,398,824	8 31
Algeria	1909	3,595,088	8 16

The colder wheat-growing countries depend almost exclusively on the slow-growing but heavy-yielding winter wheats; whilst our normal hot, dry climate shuts us out from the use of any but the fast-growing but light-yielding spring types of wheat. There is no doubt that we are able to excel where quality of grain is concerned; but in the matter of mere quantity there are certain fixed limits in the way of general averages which we cannot hope to exceed. If the Lower North as a whole were to average out 16bush. to the acre, good year, bad year, we should be doing very well. Twenty bushels as a general average for a number of years is, however, I believe, beyond our reach, although no doubt easily enough attainable in special circumstances and in individual cases.

CAN THE ASSOCIATION WITH WHEAT OF OTHER CROPS INCREASE THE AVERAGE NET RETURNS FROM LAND?

¶ If we cannot anticipate much in the way of a profitable increase in the average returns from wheat, the question arises as to whether the associa-

tion of other crops with wheat may not help to increase the average net returns from arable land. In this connection various types of forage crops are generally recommended wherever livestock operations are associated with the growing of crops. And no doubt these forage crops have in this direction much to recommend them, as many of us have found. But it is not with forage crops that I am concerned to-day. I believe—and I shall endeavor to show on what grounds—that on many farms of the Lower North if Six-row barley were grown in conjunction with wheat the average net returns from arable land would be appreciably raised.

WHAT IS SIX-ROW BARLEY ?

Let me first indicate what I understand by Six-row barley. You will be aware that on opposite faces of the ear of barley there are usually from 12 to 16 sets of three flowers, placed regularly one above the other, and occasionally more. In some barleys the two lateral flowers abort, and the central flower alone sets, giving rise eventually to a characteristically plump, well-developed grain. In the end, therefore, ripe ears of barley of this type carry only two parallel rows of grain ; these constitute the Two-row barleys, and are commonly known among us as Malting barleys or English barleys. With these barleys we are not, however, concerned to-day ; for, whilst their value is undeniable in the cooler districts of the State, I am not of the opinion that they are generally adapted to the districts we have under consideration.

In Six-row barleys each individual flower in the set of three, sets and develops ultimately into grain ; in the end, therefore, on the mature ear we have six parallel rows of grain. It is the time-honored local custom to class these barleys as " Cape barleys." I have neither seen nor heard of this name elsewhere, and I am at a loss to account for its origin. It is sometimes customary to subdivide Six-row barleys into Square-headed and Hexagonal-headed varieties, according as the central grain tends to crowd out more or less the two lateral ones. These distinctions, however, need not worry us for the present, since we are concerned mainly with the Square-headed varieties, which, so far as I am aware, are the only ones grown in Australia. It will be understood, therefore, that by Six-row barleys I mean those generally referred to here as Cape barleys.

THE ADAPTABILITY OF SIX-ROW BARLEY TO OUR CLIMATE.

So far as climate is concerned, it will be found, I think, that in South Australia Six-row barleys will thrive wherever wheat has been found to do so. That these barleys are quite as drought-resistant as wheat, if indeed not more so, there is not the slightest doubt in my mind. In Egypt, in the immediate neighborhood of Alexandria, the average yearly rainfall is about 7 in., and it is found there that Six-row barley is the only crop that can be grown satisfactorily without irrigation. In Tunisia and Algeria Six-row barleys altogether displace wheat in the hot dry agricultural areas in closest

proximity to the Great Sahara Desert. This power to withstand drought, Six-row barley owes very largely to its rapid growth and its ability to ripen off its grain in a shorter period than the earliest of wheats. With a view to illustrating this point I have looked up the Roseworthy records on the subject. I find that in the period of six years, extending between 1906 and 1911, King's White wheat—the earliest wheat we have—averaged 126 days between germination and full bloom; and that Square-headed barley—one of our selected varieties—averaged exactly the same number of days between these two periods of vegetation. On the other hand, whereas in the same period of years, between the full bloom of King's White and the ripening of its grain there elapsed an average of 59 days, this period was shortened to an average of 38 days in the case of the barley. And we all know that in a period of 12 days much may happen in the course of a hot summer that may prove detrimental to the perfect development of the grain. In brief, then, in the opinion and experience of those countries in which Six-row barleys are chiefly grown—namely, North Africa, Asia Minor, Southern Europe, &c.—they are looked upon as hardier than wheat under droughty conditions of climate. I am quite aware that this is contrary to British views on the subject. It does not appear to me, however, that these views can weigh down the evidence of countries in a far better position than Great Britain to judge where matters of drought-resistance are concerned.

Barley is reputed to fear frosts, and no doubt in this direction the resistance of wheat is greater. I am not aware, however, that as a rule frosts are sufficiently severe to the north of Adelaide seriously to interfere with the good growth of barley. In districts in which the winters are unusually cold barley will not make much growth in the winter months, and should, in consequence, be sown earlier than would be advisable elsewhere. But I cannot conceive of a winter here sufficiently severe to destroy a well-established crop of barley.

THE REQUIREMENTS OF SIX-ROW BARLEY IN THE MATTER OF SOILS.

In the matter of soil barley is as easily satisfied as wheat, where mere growth is concerned. It has, however, its predilections, particularly in the matter of yields and quality of grain—but so has wheat, for that matter. If wheat may be described as the cereal thriving best on the heavier types of calcareous loams, and rye on the lighter sandy soils, barley may be said to be seen to best advantage on soils intermediate to the two. The quality of the grain is good, and the yields frequently excellent in light mallee land of limestone formation, and in all similar types of soil. Great natural or artificial fertility in the soil is not essential to the wellbeing of barley; not infrequently, indeed, they are rather obstacles in the way of heavy yields. In very rich soils, or in soils high in condition, barley is almost invariably too rank in growth for either heavy yields or good grain. The crop is readily lodged by rough weather on the one hand, and the ears are apt to blight off

on the first touch of summer on the other. In these conditions, whilst the grain may be abundant at harvest time, it is generally small, pinched, weighs very light, and is of low commercial value. Mishaps of the kind are of more frequent occurrence in heavy than in light soils, and particularly so in all soils rich in organic matter, in which barley yields abundant green forage, but very poor grain. On the whole, therefore, for the best results barley should be placed in soils of medium consistency and moderate fertility.

POSITION OF SIX-ROW BARLEY IN ROTATION.

We are all in accord as to the position that should be given to wheat in any rotation in which it is made to enter. It must be preceded either by bare fallow or by a crop calculated to improve the general fertility of the soil, to crowd out and prevent the seeding of weeds, and to leave the soil in a condition that permits of the preparation of an adequate seed bed. Six-row barley is, in this connection, far less exacting than wheat; and the fact that, if anything, it fears an excess of fertility, enables it to follow with advantage a crop that has already partially exhausted the available fertility of the soil. There are few weeds, too, that a well-grown crop of barley cannot crowd out and get the better of. Nor is that consolidated seed bed, that it takes us so many months to build up for wheat, essential to the success of barley. It is for these reasons, therefore, that, in my view, there is no crop that follows wheat, that has been preceded by a year of bare fallow, to better advantage than Six-row barley. And I venture to suggest, as likely to prove more profitable on many a Lower North farm than the rotations usually in use, the following alternative rotations:—(A) First year, bare fallow; second year, wheat; third year, barley; or (B) first year, bare fallow; second year, wheat; third year, barley; fourth year, pasture.

PREPARATION OF THE LAND FOR SIX-ROW BARLEY.

No particular difficulty offers in the preparation of land for Six-row barley following on a crop of wheat or wheaten hay. The wheat or hay stubbles can first be grazed over and trampled under foot by livestock; or if this is not possible, they can be burnt down. The first breaking up of the stubbles would take place in February and March: a time of the year when time is apt to hang heavy on the wheat farmer's hands, and when his teams are doing little or nothing towards earning their living. The plough—as indeed should invariably be the case in all forms of summer ploughing—should be followed as speedily as possible by a heavy land-roller, or preferably by a clod-crusher of the Crosskill type. Where possible, the area ploughed up in one day should be rolled in the same day, or the day following. Cultivators and harrows will complete the work, and reduce the land to a suitable condition of fine tilth. For, be it recollected, that if a consolidated seed bed is not essential to the success of barley, one that is finely divided is. There

is an old French proverb to the effect that whilst wheat should be sown in mud, barley should be sown in dust.

SEEDING OPERATIONS.

Here, again, at seeding time, in the matter of distribution of work, barley dovetails in admirably with wheat. According to circumstances, it may be sown either before or after the latter. Under our usual conditions of climate Six-row barley is, as a rule, better sown somewhat late in the season, and after wheat—towards the latter end of May and the beginning of June, in the Roseworthy district, for example. If sown much earlier the crop is apt to become over rank and winter-proud; and, in the end, both quality of grain and yield are the sufferers. In any district, on the other hand, in which the average winter temperature is sufficiently low seriously to hinder the winter growth of barley, earlier sowing might perhaps be resorted to with advantage, in order that the plants may get a good grip of the soil before the cold weather sets in. Even in normal localities very early sowing of barley may be resorted to without ill effects, providing the precaution be taken to feed off the crop heavily with sheep once or twice, according to the requirements of the season. It is worth noting in connection with early sowing that barley does not fear that half-moist condition of soil which invariably leads to the malting of wheat grains. In seasons that open unfavorably, therefore, it may be sown whilst wheat seeding operations are suspended, particularly as it has little to fear from the competition of weeds that will germinate with it.

At Roseworthy, 50lbs. to the acre is our usual standard rate of seeding for Six-row barley; occasionally, when the field is known to be very dirty, we use as much as 70lbs. to the acre. In a general way, however, thick sowing is not to be recommended for barley. Its principal objection is an increased tendency in the crop to lodging. As a matter of fact, Six-row barley stools very freely, and there is very little to be gained in forcing the quantity of seed sown.

Barley can be drilled in deeper than wheat, although in ordinary circumstances there is nothing to be gained in exceeding the 2in. limit.

MANURES.

In the matter of manures the local requirements of barley are very much the same as those of wheat. Hence, in our soils, barley should be drilled in with the quantities of superphosphate that have been found to answer best for wheat. I have already adverted to the fact that too much available nitrogen in the soil is, if anything, more or less detrimental to barley. It represents, however, a contingency that must always remain of rare occurrence where barley is made to follow immediately in the wake of a wheat crop. When barley is sown on very light sandy land a dressing of from $\frac{1}{4}$ cwt. to

$\frac{1}{2}$ cwt. of sulphate of potash to the acre, drilled in before seeding, will often prove necessary.

AFTER-TREATMENT OF BARLEY.

Between seeding and harvesting operations there will be little or nothing to be done to a well-grown crop of Six-row barley raised under the conditions indicated. In certain circumstances, if it is thought necessary, the crop might be harrowed or rolled, or subjected to both operations. At Roseworthy, although we have been growing barley with success for many years, we have rarely had occasion to roll or harrow a barley crop; although where wheat is concerned either or both operations have frequently been found necessary.

In spite of all precautions, however, particularly in years of mild frostless winters, a crop of barley may show a tendency to run away from itself and become over-rank in growth. When such is the case one should never hesitate to feed off with sheep a crop of barley; for there is no crop that can be fed off with greater impunity nor which responds better to the treatment. By way of caution it should be added that it is not wise to feed off a crop of barley at a time when a spell of cold frosty weather has set in. In similar circumstances I have known a barley crop never to recover from feeding down. In brief, whilst I am not of those who hold that any and every crop benefits, no matter what the circumstances, by being promiscuously fed down, I am strongly of the opinion that for success at harvest time every rank crop of barley should be fed down heavily with sheep, particularly if it should happen to have been sown somewhat early in the season.

HARVESTING OPERATIONS.

I suppose I shall be told that barley is far more troublesome to reap than wheat; and I shall admit the impeachment if stripper or complete harvester are to be turned into a rank-grown, badly-lodged crop of barley which had not been fed off in the winter time. These, however, are contingencies that should have been foreseen earlier in the season, and forestalled accordingly. The stiff awns, too, are no doubt apt to choke both reaping and cleaning machinery, particularly if the crop be at all heavy. I do not know, however, that troubles of this kind are not the natural consequences of lack of experience in handling an unfamiliar crop, and that increased experience only is needed to make the rough ways smooth. I have, at all events, heard a neighbor of ours, who always puts in a little barley, state that with a complete harvester he could always undertake to make a better sample from a crop of barley than from a corresponding crop of wheat. On the whole, I think it will be admitted that these harvesting difficulties cannot be classed as insuperable; and if they constitute the only obstacles in the way of a more extensive use of Six-row barley as an ordinary farm crop I have no fears as to what is likely to be its future in our midst.

**THE AVERAGE NET RETURNS FROM A ROTATION IN WHICH WHEAT IS
ASSOCIATED WITH SIX-ROW BARLEY.**

I have now indicated the lines along which I imagine that Six-row barley can be utilised by us to best advantage. I have also stated my conviction that its more general use on Lower North farms will lead to an increase in the average net returns from arable lands. I shall now proceed to show the extent to which I imagine that this is likely to be the case. For the purpose I shall take the three-year rotation suggested by me, viz.—(1) Bare fallow, (2) wheat, and (3) Six-row barley, which, in so far as average net returns are concerned, must be compared with wheat and bare fallow alternating continuously. It should be added that the same arguments will hold good where a year's pasture is made to intervene every third or fourth year.

I shall, in the first place, assume that the cost of putting in and taking off a crop of Six-row barley remains approximately the same as that adopted for wheat, viz., 40s. an acre. Such, at all events, is our experience.

As in the case of wheat, average gross returns are dependent on average yields and average prices. Unfortunately, the returns from the Statistical Department have not distinguished until quite recently between Cape or Six-row barley on the one hand, and English, Malting, or Two-row barley on the other; and in my experience the yield of Six-row barley is, under our conditions of climate, between 25 per cent. and 33 per cent. higher than that of Two-row barley. I find that between 1901 and 1911 the aggregate yield of these two types of barleys was represented for the State by 16bush. 23lbs. Over the same period I have already stated that the average yield of wheat was represented by 9bush. 13lbs. We have, however, grown Six-row barley on the College Farm fairly extensively for the past eight years, and a careful record of its average yields has been kept. I have summarised below, in Table III., details concerning these average yields of Six-row barley comparatively with those of wheat on the College Farm.

*TABLE III.—Showing Average Returns from Wheat and Six-row Barleys
at the Roseworthy Agricultural College between 1904 and 1911.*

Year.	Rainfall.		Barley.			Wheat.		
	"Useful."	Total.	Area.	Yield		Area.	Yield	
	April- November.			per Acre.			per Acre.	
	Inches.	Inches.	Acres.	Bush.	lbs.	Acres.	Bush.	lbs.
1904	11-00	14-70	27-86	38	33	330-00	18	3
1905	14-23	16-71	65-73	25	4	212-00	24	11
1906	16-30	19-72	51-00	40	38	318-00	14	30
1907	13-81	15-05	79-30	31	21	178-00	13	20
1908	15-53	17-74	94-83	43	49	258-00	22	14
1909	21-15	23-05	75-27	35	0	328-47	25	5
1910	16-79	23-87	113-42	37	9	267-35	16	38
1911	8-19	12-42	76-09	39	31	234-98	14	17
Means for eight years (1904-11)	—	—	—	36	23	—	18	32

It will be seen, therefore, that from 1904 to 1911 Six-row barleys averaged on the Roseworthy Agricultural College Farm 36bush. 23lbs., whilst in the same period of time wheat averaged 18bush. 32lbs., *i.e.*, Six-row barleys yielded exactly twice as much as wheat. Hence, since I have assumed an average yield of wheat for the Lower North of 16bush. to the acre, 30bush. of Six-row barley cannot be looked upon as an extravagant average to suggest. To those who are without experience of this crop, and to whom the yield may appear high, I would point out that on the College Farm we have frequently secured from Six-row barley yields of 50bush. to 60bush. to the acre, and in exceptional cases even higher. In any case, if the average yield of Six-row barley is to be reduced in these estimates a corresponding reduction must be made in the average yield from wheat, and the arguments to be derived from the higher yields will still hold good.

For reasons that I propose looking into later on, the market price of Six-row barley is subject to more frequent and violent fluctuations than is that of wheat. I find, however, that for the period of 10 years extending between 1901 and 1910 Cape barley has averaged on the Adelaide market slightly over 2s. 7d. a bushel. If, then, we adopt this figure, together with 30bush. an acre as an average yield, we shall find the gross average returns from Six-row barley to be represented by £3 17s. 6d. an acre.

We are now in possession of all data necessary to establish a comparison between the average net returns from wheat grown regularly after bare fallow, and a rotation in which a crop of wheat is always followed by a crop of barley. For the purpose we must take into consideration a period of six years, in which on the one hand we shall have three crops of wheat to our credit, and on the other two crops of wheat and two crops of barley. I have summarised below, as clearly as possible, a statement from which the average net returns may be derived in each case.

AVERAGE NET RETURNS FROM LAND ALTERNATELY UNDER WHEAT
AND FALLOWED.

	Receipts. £ s. d.		Expenditure. £ s. d.
Preparing land, putting in and taking off three crops of wheat	—	..	6 0 0
Returns from three crops of wheat	8 8 0	..	—
Balance available to meet six years' interest on capital value of land and net profit	—	..	2 8 0
	<u>£8 8 0</u>	..	<u>£8 8 0</u>

In the case, therefore, of wheat alternating regularly with bare fallow the average net returns available to meet both interest on capital value of land and net profit average out at 8s. per acre per annum.

**AVERAGE NET RETURNS FROM LAND IN WHICH WHEAT AFTER BARE FALLOW
IS SUCCEEDED BY SIX-ROW BARLEY.**

	Receipts.				Expenditure.		
	£	s.	d.		£	s.	d.
Preparing land, putting in and taking off two crops of wheat and two crops of barley	—	—	—	..	8	0	0
Returns from two crops of wheat	5	12	0	..	—	—	—
Returns from two crops of barley	7	15	0	..	—	—	—
Balance available to meet six years' interest on capital value of land and net profit	—	—	—	..	5	17	0
	<hr/>				<hr/>		
	£13	17	0	..	£13	17	0
	<hr/>				<hr/>		

When, on the other hand, a crop of barley is made to follow wheat which has been preceded by bare fallow the balance available to meet interest on the capital value of land and net profit is represented by 19s. 6d. per acre per annum.

I know very well that these figures can claim to be no more than personal estimates of the situation. I am also conscious of the difficulty of making average estimates, however well thought out, square with all the circumstances of individual cases. I do not, therefore, for a moment anticipate that all those who decide to try their hand at barley must necessarily achieve results that appear to me to represent the average possibilities of the position. I trust, however, that those who fail will not accuse me of juggling with figures; that they will recognise that my "estimates," such as they are, are based on facts that are *facts*, and that the groundwork of calculation has been indicated sufficiently clearly and fully to enable others to draw up estimates more in keeping with their individual cases. It appears to me, however, that the difference between the estimated average net returns from land of 8s. an acre on the one hand, and of 19s. 6d. an acre on the other is sufficiently great to leave ample margin for any unintentional error or exaggeration in the estimates. May I therefore express the hope and anticipation that, by some at least of those whose land is adapted to the growing of Six-row barley, these anticipated results of mine may be realised.

I propose next examining some of the objections that are sometimes raised to the growing of Six-row barley.

WHAT IS LIKELY TO BE THE POSITION OF THE BARLEY MARKET IF BARLEY WERE GROWN MORE WIDELY IN SOUTH AUSTRALIA THAN IS AT PRESENT THE CASE ?

It has sometimes been put to me—and with good apparent reason, I think—that if Six-row barley were grown at all extensively within the State it would soon become a drug on the market, which farmers would find it difficult to dispose of. If I thought that such was likely to be the case I would not dream of advocating its wider cultivation. As a matter of fact, however, I firmly believe that the reverse would be the case. I have already referred to the violent fluctuations in price to which barley is in present circumstances

exposed on the local market. These I take it to be the natural consequences of a somewhat limited local demand, and an average supply insufficient to warrant the opening up of a regular export business. In other words, as we stand at present, the barley market is like the pig market, subject to periods of glut and periods of scarcity, when, as is at present the case, the locally-grown article cannot even be quoted. Indeed so irregular and scanty are the usual local supplies that buyers, I understand, always experience the greatest difficulty in purchasing outright 100 bags or so of even sample. From personal experience I know that our usual yearly contribution to the market, of 1,000 bags or thereabouts, is eagerly competed for, and always realises higher prices than those quoted at the time in the daily press.

I do not suppose that anybody doubts that good Six-row barley, if available for the purpose, could be exported quite as readily as wheat. Whenever we have anything worth selling it is generally to the moneybags of Great Britain that we look; and in this connection I owe it to the courtesy of the Under Secretary, Mr. L. H. Sholl, that I am able to summarise below, in Table IV., recent data concerning the British imports of barley:—

TABLE IV.—*Showing recent (1907-11) Average Yearly Imports of Barley into Great Britain.*

Countries whence Consigned.	Quantities Imported. Bushels.	Values.	
		Total. £	Per Bush s. d.
Russia	18,338,880	2,432,818	2 8
United States	5,735,654	953,693	3 4
Turkey	5,668,006	895,135	3 2
Roumania	5,496,781	763,510	2 9
British India.....	1,874,083	256,720	2 9
Morocco	1,677,312	235,440	2 10
Tunis	1,093,613	177,707	3 3
Chili	936,723	160,495	3 5
Tripoli	780,102	131,392	3 4
Algeria	757,478	124,158	3 3
Canada	745,069	103,640	2 9
Austria-Hungary	630,874	130,037	4 1
Persia	470,848	61,616	2 7
Germany	329,804	66,006	4 0
France	258,191	44,928	3 5
Denmark	236,096	44,845	3 10
Cyprus	218,221	34,556	3 2
Argentine Republic	114,733	15,970	2 9
Bulgaria.....	107,430	14,819	2 9
Australia	64,467	10,688	3 4
New Zealand	48,160	8,104	3 4
Belgium	22,579	3,871	3 5
Netherlands	13,619	2,014	2 11
All other countries	143,674	24,851	3 6
Average total imports.....	<u>45,762,397</u>	<u>£6,697,013</u>	<u>2 11</u>

It will be noticed that Great Britain draws her barley supplies from all parts of the world, and that we contribute but an infinitesimal share towards

them. Between 1907 and 1911 the total British imports of barley averaged yearly 45,762,397bush., valued at £6,697,013, or over 2s. 11d. a bushel at the port of landing. In order to realise what these figures imply it is worth noting that between 1901 and 1910 the average yearly total exports of wheat (including flour expressed in terms of wheat) from the Commonwealth as a whole were represented by 29,788,653bush., *i.e.*, not much more than one-half the number of bushels of barley imported annually by Great Britain. In the circumstances, therefore, I think it will be agreed that the British market alone is quite capable of absorbing any exportable surplus of barley that is likely to be produced by South Australia within our times.

It may perhaps be thought that the imports into Great Britain of barley may consist chiefly of the Two-row types, or malting barleys. I am pleased to be able to add, therefore, that after a careful analysis of the countries from which the barley supplies of Great Britain are derived, and with a full knowledge of the types of barley usually grown in these countries, out of an average yearly total approaching 46 million bushels, between 35 and 40 million bushels are almost certainly of the Six-row barley type.

I trust that these statements will serve to dispel the fears of those who appear to anticipate that large areas under barley would give rise to a difficult market position.

IS THE PRESENCE OF BARLEY HEADS IN THE WHEAT FIELD NECESSARILY CONNECTED WITH THE GROWING OF BARLEY ON THE FARM ?

Nobody is particularly pleased to see vigorous barley heads waving over a wheat field, and it is stated that if we allow barley to be grown in regular rotation with wheat the wheat field will never be free from stray heads of barley. I entirely disagree with this view, and can speak from the standpoint of eight years' experience in the matter. For the last eight years we have grown barley on the Roseworthy Agricultural College Farm fairly extensively; and we have not only grown the crop, but we have also fed the grain regularly to pigs—and occasionally to horses and cows—and the manure has found its way into the fields. Notwithstanding this, I think that I can fairly claim that our wheat fields are quite as free from barley plants as those of our neighbors who neither grow nor handle barley. I am strongly of the opinion that this should always be the case with ordinary care whenever wheat is separated from barley by an interval of a year's bare fallow, and particularly so if a year of pasture is additionally made to intervene.

The precautions to be taken to prevent the promiscuous distribution of barley over the land are elementary enough. Seeding, harvesting, and cleaning machinery should always be thoroughly overhauled when passing from barley to wheat; and barley grain fed to livestock should always be crushed, soaked, or steamed. Seed supplies, however, is the most common

channel through which barley finds its way into the fields; and I find that we are rarely able to escape contagion when we sow oats, the seed of which we are compelled to purchase from outside sources. If ordinary seed, however, be put through a modern grader the great bulk of barley grains can be very readily removed. May I point out here that, in my view, an efficient seed grader is an essential part of the plant of every well-equipped farm that is too often overlooked? The price of a good grader is perhaps beyond the means of a small farmer, who could put it to very limited use only. Might I suggest that individual Branches of the Agricultural Bureau might with great advantage to themselves and the State purchase jointly one seed grader, which could be used by the various members in rotation between harvesting and seeding operations?

Let me then assure you, on my own personal experience, that the farmer who grows barley is not under compulsion to advertise the fact in his wheat and hay fields.

DOES A HEAVY CROP OF BARLEY EXHAUST THE CONDITION OF THE LAND SUFFICIENTLY TO AFFECT THE YIELDS OF WHEAT FOLLOWING TWO OR THREE SEASONS LATER?

I have been told by some that in their experience a heavy crop of barley had the effect of reducing the yields of the wheat crops that followed. In reply to this, all that I can say is that I have been growing heavy crops of barley for a number of years, and cannot say that I have observed this to be the case. A crop may fail more or less for a variety of reasons, and it is possible that we have here a case of mistaken conclusion. It is true that barley is surface-rooted to a greater extent than wheat, and it is possible that if a 3in. to 4in. furrow is never exceeded at fallowing time the wheat plant may suffer from having to depend too exclusively upon the surface layers, already depleted of their available fertility by the preceding barley crop. If such be the case, the remedy is obvious—fallow deeper after a good barley crop.

IS THE ADMITTED LIABILITY OF BARLEY TO LOOSE SMUT AN INSUPERABLE OBJECTION?

It is admitted that barley is very subject to attacks of loose smut, and that it is no easy matter to free smutty seed from the spores of the disease; nor is it difficult to realise why this should be so. In the first place, in the early summer, when the atmosphere of a smutty field is fairly permeated with the impalpable black powder, the husks of the sound grains have not yet closed down firmly on the grain which they enclose, and it follows that some of the minute spores may penetrate between the outer husk and the seed, where they will continue until the grain germinates. No amount of external pickling can possibly reach them, with the exception,

perhaps, of the hot water method, which in ordinary circumstances can hardly be looked upon as a practicable method of pickling. Again, the grain of barley, with its coarse outer husk, is far rougher than the naked grain of wheat, and unless very carefully pickled it is not possible to reach even those spores that adhere to it externally. It is, in my opinion, idle to imagine that the mere fact of dipping a bag of wheat into a solution of blue-stone and then allowing it to drain, will have the effect of destroying all the spores adhering to the grains. These grains may be described as being more or less greasy, and protected from complete contact with the liquid by a coat of air bubbles, which shield the smut spores from contact with the poisonous fluid. Unless these grains are repeatedly and thoroughly stirred up they have not the slightest chance of becoming completely wetted, and therefore pickled. If this is true of wheat, it is all the more so of barley grains, protected as they are by a rough, coarse husk.

My own view on the matter is that for barley it is essential to secure seed from a field known to have been quite free from smut, and that pickling can never absolutely be depended upon. Some seven years ago we had a crop of barley that could not have been affected by smut to a greater degree. Since that time it has been a difficult matter to discover a single smutty head in all the fields. I attribute our success in this direction to the use of seed derived from our hand plots, which are naturally quite free from smut.

SIX-ROW BARLEYS FOR MALTING PURPOSES.

We are generally inclined to look upon the grain of Six-row barleys as suitable for feeding and fattening livestock only, and we give emphasis to our views by describing them as "Feed barleys," whilst for the grain of Two-row barleys is specially appropriated the term "Malting barley." That weight for weight and volume for volume the grain of Two-row barleys has greater value to maltsters than the best grain of Six-row barley need not be disputed; the proportion of husk, or waste, is invariably heavier in Six-row barley, whilst the proportion of carbo-hydrates—the most valuable ingredient in malt—is correspondingly lower than is the case in the average grain of Two-row barley. These facts notwithstanding, however, if we take the world as a whole, we shall find that there is quite as much malt made from the grain of Six-row barley as from that of Two-row barley, if, indeed, not more; and that good, well-grown grain of Six-row barley has its value in that direction is, I believe, beginning to be more generally recognised in Australia. When we see good Cape barley quoted at 3s. 6d. to 5s. a bushel, as was the case last season, we can rest assured that it is the maltsters and not the livestock holders who are after it. This is a fact that is well worth bearing in mind, for the price paid for a malting barley is quite other than that which can in ordinary circumstances be paid for a "feed barley." It is true that even for the best possible sample of Six-row grain we cannot anticipate

realising altogether the prices paid for the plump, thin skin grain of the Two-row barleys. We are, however, entitled to expect as much as 1s. a bushel more than is usually paid for ordinary Feed barleys. Hence, in our estimates of average net returns the average price for good Six-row barleys is likely to be nearer 3s. 6d. a bushel than 2s. 7d., the average figure which I adopted.

On the other hand it must be recognised that much of the Six-row barley grown is fit only for feed purposes. This is the case of all the thin, but thick skin, discolored, leathery grain that is often met with. Briefly, the characters essential to a good malting sample may be summarised as follows:—The grain must be even in character, so as not to leave too great a proportion of refuse on grading and cleaning. It must be plump and well-rounded and filled; pale-yellow and bright in color, not dull or discolored, with a soft floury cross section, and not hard and steely. A good malting sample calls for particular attention in harvesting operations. It is absolutely essential that the grain be perfectly sound, with its germ or embryo uninjured, since everything depends on a good, even germination on the malting floor. Broken grains, whilst useless to the maltster are not fatal to the sample, since they can be removed in the cleaning process; but sample showing a heavy percentage of cracked grains, or grains the embryo of which has been more or less injured, are quite useless for malting purposes. And the same may be said of a sample that has been seriously affected by rain during harvesting operations. In the latter case the sample would be more or less discolored. It is not essential that all traces of the awn be removed from the grain; indeed, over-thorough dressing of the grain in this direction is generally fatal to the malting quality of the sample.

No doubt climatic conditions—both general and those peculiar to any given season—have much to do with the quality of a malting sample. There are seasons that are unfavorable, just as much as there are localities that are unfavorable to the production of good malting grain. In a general way those seasons in which summer weather sets in suddenly, with abrupt changes from cool overcast conditions to hot northerly winds, are generally detrimental to the quality of the sample. The grain, as a rule, remains pinched and ill-developed, tough, thick, and leathery in the husk—it has ripened off too suddenly. Heavy rains at harvest time are almost equally detrimental. The most favorable conditions are those leading to a gradual and slow ripening of the grain and bright, dry, sunny days for harvest time. It is said by maltsters that much of our Cape barley is useless for malting purposes. I cannot believe that this is either wholly or generally connected with our climatic conditions. Great Britain draws much of her malting barley from countries equally hot and dry—from North Africa, from Asia, from California, &c., and the quality of sample which these countries can grow we can surely grow too.

Soils and their condition, and methods of cultivation, have also much to do with the ultimate quality of the sample. Anything leading to rankness of growth in the crop is certain to affect the grain detrimentally. I need not, however, dwell on this point, since I have already dealt with it fully higher up.

Finally, the variety of barley grown has much to do with the quality of the grain. At Roseworthy we have had in hand for the past seven or eight years three varieties of Six-row barleys. All three look almost equally well in the field. One of them, however—perhaps the best in the matter of field appearances—invariably yields a rather inferior sample, whilst the reverse is the case with the other two.

By way of conclusion on this aspect of the question, I shall state that, whilst we may not always be able to produce a perfect malting sample, the attempt is always worth making if the high prices realisable be taken into consideration.

SIX-ROW BARLEY FOR FATTENING PURPOSES.

However unsuited for malting purposes the grain of Six-row barley may be, it will always retain its feeding value for livestock; and in this connection in times of low prices, shall we not find it to our advantage not to sell it in kind, but to transform the grain into animal tissues, the money value of which is generally much higher. Apart altogether from the profit we may hope to derive from the fattening increase of our livestock, we shall retain on the farm rich manure which will go towards building up afresh the fertility of our soils, upon which the unavoidable practice of bare fallowing is drawing so heavily. Indeed, so important is this side issue, that if at current rates our feeding accounts only just balance, without leaving any very appreciable margin of profit, the indirect benefit of increasing soil fertility and swelling crop yields will amply compensate us in this direction. Five or six pounds of grain will, in ordinary circumstances, lead to 11lb. increase in live weight of pigs. Hence, it is an easy matter to calculate whether or not feeding is likely to prove profitable at ruling rates. Barley, at 2d. 1s. a bushel, works out to $\frac{1}{2}$ d. a pound. Hence, 11lb. of pork would be produced at the cost of 2 $\frac{1}{2}$ d. to 3d., without taking into consideration the manure produced, which may be set off against any labor that may be entailed. I take it that in ordinary circumstances, whenever barley is worth 2s. a bushel or less, it can be fed to pigs at a good profit. Even at higher rates, when helped along with odds and ends, the speculation should prove a profit-bearing one.

Naturally, when grain-feeding is being considered, barley challenges comparison with wheat. No doubt, weight for weight, wheat is superior to barley as a foodstuff. Roughly, in the proportion of 8 to 7, i.e., 7lbs. of wheat should go as far as 8lbs. of barley. Whether the one or the other can be fed to best advantage will depend exclusively on the relative ruling prices

for each. I have worked out below what would be the corresponding monetary value of barley as a foodstuff relatively to the market values of wheat, varying within the limits that we have been accustomed to within recent years.

TABLE V.—*Showing Money Value of Barley as a Foodstuff Corresponding to an Ascending Series of Wheat Market Prices.*

Market Value of Wheat per Bushel of 60lbs.	Corresponding Value of Barley as a Foodstuff per Bushel of 50lbs.	Difference.
s. d.	s. d.	s. d.
3 0	2 2½	0 9½
3 1	2 3	0 10
3 2	2 3½	0 10½
3 3	2 4½	0 10½
3 4	2 5½	0 10½
3 5	2 6	0 11
3 6	2 6½	0 11½
3 7	2 7½	0 11½
3 8	2 8	1 0
3 9	2 8½	1 0½
3 10	2 9½	1 0½
3 11	2 10½	1 0½
4 0	2 11	1 1

Roughly, then, at normal rates, and from the point of view of its feeding value, wheat is worth about 1s. a bushel more than Six-row barley. When the difference between the market values of the two is greater, barley will represent better feeding value of the two; when the difference is less than that indicated in Table V. wheat can be fed to greater advantage than barley. When, however, the difference between market values is approximately normal, and both wheat and barley are available, it will be good practice to make alternate use of both cereals, by way of variety in diet; since animals, particularly when on fattening regime, quite as much as ourselves, need the stimulus of variety to stir up their jaded appetites.

BARLEY IN THE RATIONS OF WORKING HORSES.

There is a last use for which I intend recommending Six-row barley, and that is an occasional place in the rations of our working horses. I regret much that this point should come up towards the close of a tediously long paper. In justice to my audience I can do no more than indicate the controversial matter that is involved in the discussion; and yet the feeding of our working horses is a subject on which much might be said, and I must say it briefly. First, let it be understood that I have no intention of questioning the supremacy of oats among recognised horse foodstuffs. If I were placed in a locality in which oats could be raised as well and as cheaply as Six-row barley, I should unquestionably give the preference to oats as horsefeed. But, in our experience, heavy yields of grain at all comparable to those of barley can be obtained from oats only in exceptional seasons; and I take it that many portions of the Lower North are similarly situated.

In this connection, therefore, it is for the localities in which oats—essentially a moist cold-country cereal—are more or less precarious as grain crops, that I am speaking.

Those who advocate the use of corn in the rations of working horses are, in this country, faced with two stumbling blocks—(1) the well-nigh universal practice of feeding chaffed wheaten hay exclusively to horses, and (2) the prejudice that corn of any sort, but particularly barley, is heating and injurious to horses. This last trait is supposed to be peculiar to the horses of hot countries, for which wheaten hay is supposed to represent the only possible foodstuff. Now, I must confess that this prejudice—for I can call it nothing else—surprises me not a little. Is it realised by those who hold these views that Australia is perhaps the only country feeding on a large scale wheaten hay to its horses? Before coming out here I lived in a country quite as hot and dry as South Australia, if not more so, in which working horses were fed on nothing else but barley and long straw. Indeed, this is the practice throughout the north of Africa, in Asia, in Southern Europe; in fact, in all countries in which oats cannot be raised to great advantage. What, then, is the matter with the average constitution of our horses that they are said to grow ill at the unwonted sight of corn? Want of use, I fear; and I am persuaded that if they were led up to corn rations gradually they would thrive on them quite as well as the horses of other hot countries. In this connection I may, I think, quote a recent example taken from the working horses of the Roseworthy Agricultural College Farm. In a general way we have hitherto adhered to local custom, and fed our horses very largely on wheaten chaff, and wide have been the areas cut down each year to meet their requirements in this direction. In the present season, however, total absence of natural feed down to spring time unexpectedly threw upon us the hand feeding of 1,552 sheep and 52 head of cattle, in addition to a handful of colts and young horses. I soon perceived that our hay supplies would not hold out against the unforeseen drain put upon them. I was determined not to purchase hay; and consequently our working horses were put upon a regular corn ration, with a little chaff and plenty of long straw; and, in the opinion of the farm manager, they have never been in better fettle, nor have they ever stood the heavy winter work better.

I am not disputing the value of wheaten hay as horse feed. There is ample experience to show that horses will do slow heavy work tolerably well on wheaten chaff alone. As a rule, however, they lack the energy and go of corn-fed horses. My contention is that, even if corn is not habitually fed to horses, in times of drought and high prices barley grain and straw will generally prove a more economical ration than good wheaten chaff. I assume that a draught horse on working allowance will put away with ease a 40lb. bag of chaff a day, of a value of about 1s. at average prices, and considerably more in times of drought. In North Africa a light horse usually

receives about 12lbs. of barley grain a day, distributed in three meals, together with as much long straw in an overhead rack as he cares to take. A heavy draught would probably require about one-half more, *i.e.*, about 18lbs. a day. With barley at 2s. a bushel 18lbs. would represent a value of little above 8½d.; not quite 11d. with barley at 2s. 6d. The grain, therefore, would cost no more than the 40lbs. of chaff at normal rates, and considerably less than the chaff when hay is soaring up to £4 and £5 a ton. True, straw must be supplied additionally in the way of bulk food. This, however, can very readily, and at comparatively little cost, be stacked on any farm on which both wheat and barley are grown; and it should be noted that livestock generally are more partial to barley straw than to that of wheat.

CONCLUSION.

Gentlemen, this question of Six-row barley is no new infatuation of mine. Twenty years ago I left a country in which barley is grown quite as extensively as wheat, and when I came to Roseworthy it appeared to me that the locality was particularly well adapted to the growing of barley. This view I urged upon Professor Lowrie at the time, and he authorised me to import for him some Tunisian barley, which appeared to me superior to the type usually grown here. In those days, however, the superphosphate question had not yet been solved, and Professor Lowrie was too much absorbed in wheat problems to give much attention to the minor cereal; hence nothing came of the venture. Eight years ago I took up the question a second time; and I think I can claim to have demonstrated that both heavy and very remunerative crops of barley can be raised in the Roseworthy district. When I made up my mind to bring up the subject of Six-row barley before Congress I realised fully the difficulty of bringing home to others what is clear as daylight to oneself. I do not know whether I have succeeded in convincing you; nor even if I have treated my subject in the manner most likely to do so. Let me hope, however, that I have interested at least some of you. If I have done so, I am confident that not many years will pass before others in their general practice will be able to show that I have not been over-sanguine in my advocacy of Six-row barley as an aid to the profitable farming of many of our districts. (Applause.)

THE DISCUSSION.

Mr. D. B. Butler (Butler) desired to know whether Six-row barley could be grown on the average mallee land as cheaply as Algerian oats.

Professor Perkins said that at Roseworthy the experience was that they could grow more barley than Algerian oats on the same terms.

Mr. B. Correll (Minlaton) had grown barley, and he strongly recommended all farmers to give it a trial. It was the most profitable second crop that could possibly be grown after wheat. It could be followed up with bare

fallow, or better still, the barley stubble could be left out for one year for grazing, thus providing good feed for lambs. The straw went down very readily, and was easily ploughed in for the purpose of adding humus to the soil. He had secured as much as 30bush. to the acre, and last year he reaped a crop of 47bush. to the acre. Owing to the fact that it lodged badly, it was rather wasteful. Where good cultivation was practised good yields would be secured. It was a mistake simply to drill the crop on the stubble.

Mr. B. McCallum (Willowie) said the Willowie Plains were capable of producing crops of from 35bush. to 50bush. to the acre. The reason the growing of barley had been discontinued in the district was that it got into the wheat crops. (Applause.)

Mr. J. Darley (Narridy) said last year there was a shortage of feed in the district. About the 27th of August he drilled in a small plot of English barley on fallowed land. It came away well, and despite the fact that not more than 1½in. of rain fell, he reaped a yield of 36bush. to the acre. He desired to know whether the English would not be better than the Six-row barley.

Professor Perkins replied that the English did not yield so well as the Six-row barley.

Mr. H. C. Williams (MacGillivray) inquired what crop should follow barley on new land.

Professor Perkins recommended the following rotation:—Bare fallow, wheat, barley, pasture. Barley always shook out, and there was earlier feed on barley stubbles than anywhere else.

Mr. D. Carmen (Pine Forest) said that there was a general belief that barley impoverished the land for wheat-growing. There would have been a great deal more barley sown in his district but for this fact.

Professor Perkins had not noticed any reduction in the yield of the wheat following barley. For eight years he had been growing barley and nothing of this nature had been perceptible. They had a rotation of turnips, barley, peas, and wheat constantly. After eight years the average yield of the wheat was very nearly as good as the average of wheat grown after bare fallow every year. The difficulty might be that the land was being worked too shallow. At Roseworthy this year there was a field under wheat. Two years ago it had carried barley, and now it showed up as the best crop they had.

Mr. D. B. Butler (Butler) had tried barley on new mallee land, and found that it weakened the soil more than wheat, and it was not nearly so good as oats for assisting in killing the shoots.

HOW TO IMPROVE THE BUREAU.

Mr. G. G. Nicholls, Secretary to the Advisory Board, stated that at present there were 140 Branches with about 3,000 members of the Bureau scattered over the State. However, there was room for more, not only in the outlying

districts, but in the more settled and populous areas. Every farmer should be a member of the Bureau. It had taken 24 years to build the institution to what it was to-day, but there was no reason why its membership should not be doubled during the next five years. Whether or not this was effected, rested with the farmers themselves. The Advisory Board could not do it unaided. The Bureau had been a factor in the improvement of farming methods, and they should not overlook the fact that the quality of the farming affected the value of the land. Many improvements in conditions under which the farmers were working were due to the influence of the Annual Congress of the Bureau. They, however, might just as well face the facts. It was a fact that the majority of Branches were doing good work, but there were two or three which seemed to be suffering from a kind of sleeping sickness (laughter), and four or five others seemed to be in the need of some treatment for the resuscitation of the apparently dead. He trusted if any delegate had the misfortune to belong to a Branch of either of the two classes he had mentioned they would see that, so far as their particular Branch was concerned, an alteration was made.

A GOOD SECRETARY.

To have good Branches they must have good meetings, and to get good meetings they needed a good secretary. He had noticed that one Branch had given their secretary a gold medal for two years' good service. That Branch had done well. There was represented at that Congress a Branch in a district which was said by its members to be a stonethrow from Western Australia. Two years ago the average attendance at the meetings of that Branch was four, now it was 19. (Applause.) That was one result of getting a good secretary. Then they must have good papers, and if there were two sides to the question it was well to have two papers read, one from one point of view and the other the opposite. The plan of having a programme committee, which had been adopted by several Branches, was a good one. The Lameroo Branch had a report day, and it had proved such a success that it was worthy of adoption by other Branches. At the close of harvest, when the results were tabulated, the members of that Branch met and had a practical discussion in regard to them. Having got good meetings, if their Branch was not a large one, they should get more members. They should not go about it the other way, trying to get increased membership and then good meetings. If a Branch was languishing it would pay the members to devote one evening to a discussion of the position. They should not make membership too cheap, but insist on intending members attending two meetings before they were nominated. He strongly believed in each Branch holding a social meeting once in each year. Every Branch of the Agricultural Bureau should conduct some experimental work. Last year five Branches had conducted experiments with manures and varieties of wheat, and two with

grasses and fodders. On such questions the final tests had to be made on their own farms, and members, by carrying on experimental work, would not only benefit themselves but provide subjects for interesting discussions at the meetings. The Pine Forest Branch last year had, through one of its members, conducted tests as to the quantity of manure best to apply. In every case the larger quantities used showed a decided profit. That was a matter in which they were all interested, and might well take action in the way of conducting experiments. The Agricultural Bureau was an important institution with a history sufficiently grand for every member to be enthusiastic concerning it. (Applause.)

Replying to a question, Mr. Nicholls stated that so far as the Advisory Board was concerned the membership of the Branches was unlimited. The restriction as to the number of members had been removed by the Advisory Board some time ago.

EVENING SESSION.

The evening session was attended by nearly all the delegates, and a number of visitors. Mr. A. M. Dawkins presided.

SALE OF WHEAT BY LOAD OVER WEIGHBRIDGE.

The Chairman said the question of the sale of wheat by load over weighbridge had been referred by the Advisory Board to the Branches, but replies had been received from a relatively small number. It had been, therefore, decided to bring the question before Congress.

Mr. Pontifex (Paskeville) said the question of weighing wheat by the load or in bulk was not a new question, and consequently did not require much discussion. He moved—"That this Congress urge the Advisory Board of Agriculture to take any steps which may be considered necessary in order to bring about the system of weighing wheat by the load over weighbridges."

Mr. W. G. Drewett (Paskeville) seconded the motion. The matter had been discussed by his Branch. Although at first he was not in favor of the system advocated, he had been convinced by the experience of others in Victoria and elsewhere where it was in force that it would be a good thing to introduce in South Australia.

Mr. Nicholls (Secretary to the Advisory Board) said that it having been reported that in New South Wales the Railway Department catered in some way for the weighing of wheat in bulk, he had written for information to the Under Secretary of Agriculture in that State. As a result he had been informed that the New South Wales Railway Department put down weighbridges at any station where in their opinion the traffic warranted it, but they would not consider doing so unless 10,000 bags of wheat were sent away from a station in one season. In 1910 there were 100 railway stations in

South Australia from which 10,000⁺ or more bags of wheat were trucked. He had further obtained quotations from different firms for putting down outside railway stations weighbridges capable of weighing from 10 to 12 tons. The quotations ranged from £55 to £100 per weighbridge, but the complete price would be nearer the latter figure than the former. He thought it would save time if Congress was placed in possession of those facts before the discussion on the resolution took place.

Mr. E. Hall (Strathalbyn) said that he had had personal experience of weighing wheat in bulk over weighbridges, and he was convinced that anyone who had had such experience would not favor the retention of the present system. In Victoria the weighbridges were controlled by the local councils.

A delegate pointed out that with the big loads carried to-day a 10-ton weighbridge would be of little use.

Mr. J. Smith (Hawker) opposed the motion. Even if weighbridges were provided, scales would have to be used at the stacks in order that the wheat could be tested and that not up to the standard weighed. Wheat could be received from the wagon off the scales just as quickly as it could be received from the wagon direct. Any man accustomed to weighing wheat on scales could keep two men running with the bags. He had been wheat-buying and farming for over 14 years and failed to see how the farmers would benefit by weighing wheat by the load.

Mr. J. A. Kuhlmann (Freeling) contended that if wheat was weighed over a weighbridge it would be far better for the farmers.

Mr. J. N. McCallam (Yabmana) said the question had been fully discussed by his Branch, and they favored weighing in bulk. They considered the result would be a saving in handling and of time.

Mr. J. Darley (Narriidy) said the Farmers' Union were weighing wheat over the weighbridge at the present time. He had been told by one of the directors that there was a great advantage in weighing in bulk, as the farmer got more and it reduced the risk of a mistake being made in adding up the figures. A 10-ton weighbridge, however, would not be large enough.

Mr. D. Menzie (Clare) said his Branch had discussed the question and had also obtained particulars of the working of the system in New South Wales. As a result they had decided to support the motion. If weighbridges up to 15 or 20 tons were provided, placed under the supervision of the railway officials, and so much charged per ton weighed, it would, he thought, be satisfactory to everyone.

The resolution was carried by a large majority.

MAINTENANCE OF ORGANIC MATTER AND HUMUS IN WHEAT-GROWING AREAS.

The Director of Agriculture (Mr. Wm. Lowrie, M.A., B.Sc.) delivered an address on "The Importance of Adapting our Practice to Favor the

Maintenance of Organic Matter and Humus in the Wheat-growing Areas." He said—

The question of humus in the soil arises as the result of the improvement of farming methods in relation to wheat-growing that has taken place in South Australia within the last 15 or 20 years. The value of thorough fallowing, and the fact that such thorough fallowing and working of the fallows is a means of conserving the moisture to eke out a rainfall against a succeeding season, has been appreciated by so large a proportion of the men working the land that the position now is that through thorough fallowing the stubble is worth very much less than it was a few years ago. Through some of the very best country—Freeling, Roseworthy, Balaklava, Saddleworth, &c.—the feed on the stubbles is decidedly much less than it used to be, and I take it that this is not altogether due to the season, but to the fact that the thorough working for the conservation of moisture is bringing about the condition that in the year in which the land is lying out there is not that growth of herbage that there previously was, and there is consequently some greater risk of farmers who continue it having to help their land with nitrogenous manures, which is an expensive matter.

LESSENING THE RESERVE OF HUMUS.

When you are fallowing to conserve moisture and clean the land, it is worth while to do it well. It is this well-doing that seems to be lessening the capacity of the country for carrying sheep as an adjunct to the farming. Some 180 years ago, a leader of agricultural science spoke in these terms—"Tillage is manure." We have got a little farther than that. It is the means of increasing the available elements of plant food in the soils. But under our circumstances it is the means of lessening the reserve, and it is this reserve that we will have to look after. The increasing of the reserve is just where the difficulty comes in. With new, or relatively new, land, of which very large areas are being opened up just lately, such as the land now being sold in Bundaleer, Gum Creek, Booborowie, &c., some of which constituted some of the best wheat land in South Australia, the holder is justified in taking wheat as frequently as he can do so to the best advantage economically, by proceeding in a somewhat extravagant manner, burning his stubble and alternating fallow and wheat for a few years, until he has recovered his outlay. This class of land, with a reserve of humus, can stand it.

Now that wheat is at a high price, men are attacking old farm lands, and burning the stubble, and working wheat and fallow, with an occasional year laying out. These men will find that their average will contract, in spite of all the work and skill they put into the fallows. The addition of organic matter to the soil should greatly increase the yields of the Lower North wheat districts. When you are fallowing you are burning out organic matter, and this will have to be returned by applying expensive nitrogenous manures.

The organic matter in the soil in the shape of roots, leaves, &c., is not a plant food, but it has its value, and one of the features which has enabled the Lower North to go on growing wheat so well has been the growth of stinkwort. This adds organic matter to the soil and keeps the position going. The roots of the plant open up the subsoil, they decay and leave a space into which air penetrates. The aeration is deepened, but it is in the decomposition of the plants that the greatest gain is secured.

SOME RESULTS OF DECOMPOSITION.

In any decaying brought about by whatever process, whether it is moulds, fungi, or ferments, there is yielded ammonia, carbonic acid, and the residual matter like leaf mould, which we speak of as humus. The carbonic acid is of value when dissolved in the water—the moisture in our soils—because through it increasing the solvent power of the water, more of the latent elements are dissolved and made available as plant food. It is a weak acid, but its total result over thousands of acres is very appreciable indeed. The greater proportion of one of the other products, ammonia, is immediately nitrified through the action of the ferments in the soil. It is oxidised; the ammonia is converted into what chemists call nitrate—probably in our climate it combines to form nitrate of soda, nitrate of potash, or nitrate of lime—which is very valuable from the point of view of a plant food. But after all the humus is the most valuable result of the decomposition.

FARMYARD MANURE.

Were the humus appreciated at its intrinsic value we would find very few indeed of those heaps of farmyard manure scattered all over the place, and the owners not troubling to apply it to the land. Why go to the trouble of buying artificial manure of only one kind when a good many, at any rate, have a pile of farmyard manure, the bottom of which has not seen the light for 10 years. (Applause.) I know some of you will say that applying the manure is backbreaking and slow work, and is not worth doing. That is not so; it is worth doing if done in a proper way, and since you have been fallowing so thoroughly there is all the more reason for husbanding that material which, on some farms, is being wasted. But you will say that if applied to wheat land direct it makes the crop dirty. That is true; and you also say it is applying nitrogen which you do not require, which is not altogether true. If, however, an opportunity is taken of applying the farmyard manure to crops such as rape or barley for green feed, too much of it cannot be used. It can also be carted to the field which you are going to fallow and then crop for hay. If, in that case, you put on the farmyard manure before you fallow you will find the hay go over the weighbridge all the better for it, and what is more that land will show the benefit of the manure for three or four years afterwards.

THE FUNCTIONS OF HUMUS.

Let me set out the functions of the humus theoretically. The first is that it helps to increase the capacity of the soil for retaining moisture. If you have organic matter in the soil you will find that the capacity of the soil for the conservation of moisture and also its capacity of absorbing moisture from the air is increased according to the amount of organic matter in it. Organic matter has the influence of altering the physical condition of the land. It is the means of improving the fertility by making the tilth so much better. Humus makes the soil more granular. It acts somewhat in the way that lime does: it flocculates the soil. When you have the soil aggregated into granules there is less rapid evaporation from it, and consequently there is not so much moisture pumped out of it. In addition to securing a tilth, it also indirectly is the means of the soil taking in more moisture, and holding it to better advantage. The best indication of the wheat-yielding capacity of land is the grass that grows on it. The dense herbage leaves so much more organic matter in the land for the farmer to work on.* This is the reason why good grass land is a sign of good cropping capacity.

A SOURCE OF NITROGEN.

The third reason is that it is a source of much of the nitrogen in the land. In the process of working the farmer allows the atmosphere freely into the soil, and the small forms of life that are there are so much the more active on account of having favorable conditions. These are the means of fixing nitrogen from the air, and in this way provide a direct gain of nitrogen for the crops. It is a small point in favor of the organic matter that thereby the temperature of the soil is raised. One advantage is that it is a means of economising the fertilisers that you are applying. Better advantages will be secured from phosphates if the land to which they are applied contain a sufficiency of humus. The organic acids, the result of the decomposition, help in the liberation of the salts, and saves the farmer the necessity of applying manures by opening up the reserves that are in the soil.

THE ACTION OF FERMENTS.

During the past 25 years biological science has shown that there are forms of ferments living in the soils which are directly collecting nitrogen from the air. Researches have shown that there are in our soils ferments which directly utilise the nitrogen in the air—they feed upon it—and the result is that there is a fixation of nitrogen in our soils as a result of their existence. There are some that do that work through their association with clovers, but there are others—there seems no doubt about it—that in themselves have the power to fix the nitrogen of the air in our soils independently of any plant life that may be there, provided they find organic matter to give them the necessary energy. The extent to which the soils gain by the direct

assimilation of the nitrogen of the air has not been measured in South Australia. It, however, has elsewhere been estimated that the amount the soils gained in that way is something like 20lbs. to 30lbs. of nitrogen per acre per year. We may say that a crop of 20bush. would remove in the grain 25lbs. of nitrogen and in the straw 10lbs., making a total of 35lbs. If, as is done in the majority of cases, the straw is left the amount of nitrogen fixed by their special ferments will not fall far behind the rate of exhaustion through successive fallowing and wheat-growing. And it is just that fact which saves the position and explains why we can grow wheat for a succession of years without putting back into the soil organic matter, and with the direct application of phosphates only. But I want to emphasize the fact that these ferments which are the means of increasing the nitrogen in our soils require some kind of food stuff in the soils from which they can draw their energy. If the practice of fallowing, wheat-growing, and burning the stubble goes on and no organic matter is put back into the soils, no advantage is derived from those ferments because they will have no food from which to draw the energy they require to perform their work.

A DIFFICULT QUESTION.

It is necessary, then, to keep up the proportion of humus in the soils. So much for the theory; but the practice is a much more difficult question. It is a very difficult problem to know how we in South Australia are to find a rotation of cropping that will keep a sufficient supply of organic matter in our soils when, if possible, we want each year to have a third of the land in wheat. I do not think we should aim at more; but a third in wheat is necessary to earn interest on our land values. But how to have a third in wheat and not burn the stubble, have a year fallow, and have a crop there for sheep feed to keep up the humus is a problem which will take a lot of thought before it is solved. I am not going to claim to solve it. How best it can be approached is all I intend to put forth to-night. It used to be argued that if plenty of phosphates were put on the land such a wealth of herbage would result that the organic matter would be kept up. That, however, has proved not to be the case with the man who fallows clean. When the crop is cut for hay the question is not a difficult one. The stubble can be ploughed and worked down and a crop sown for feed. It may be barley, oats, rape and mustard, peas, or in some districts Italian rye grass. There is an opening for that class of machinery which will enable the farmer to get over a big block of country in the very shortest time. If the tractors which are being introduced will enable the farmer to plough, work up, and prepare for sowing about 15 or 20 acres a day, they are the implements which South Australian conditions require. These would enable the farmers to go over the stubbles at the same time that the teams are sowing the fallows. If the fallowing is done too late there is not the addition of organic matter to the soil. Rape

can be sown at the rate of from 3lbs. to 5lbs. per acre, mixed with 2lbs. or 3lbs. of mustard. It will last longer into the season if sown thinner, but in South Australia it is wanted for the purpose of putting humus into the soils, so it is necessary to sow thickly. It can be mixed with Italian rye grass. There are many places in South Australia where this should prove one of the best of green fodders, but when sowing it is necessary to exercise care in securing the best seed. The best varieties are Sutton Giant and Western-wolths. I doubt, however, whether it will succeed on anything under a 17in. rainfall. While it would be the means of increasing the stock-carrying capacity of the land, it will not be anything like the advantage to the succeeding crop that rape or peas would be. But to make a success of growing fodder crops they must not be treated less generously than are the wheat crops. If they are sown on the stubble the land should be worked and manured well. If peas are sown they will not want farmyard manure, but should be given $1\frac{1}{2}$ cwts. to 2cwts. of phosphates. For fattening lambs I find mustard with rape will avoid risk of deaths. In districts with a good rainfall Italian rye grass and peas should certainly be tried. Peas will not only fatten your lambs but will also improve your land to an extent which few other crops can approach. (Applause.)

Mr. E. J. Pearce (Whyte-Yarcowie) said that Professor Lowrie had referred to the work entailed in placing farmyard manure on the land. There was a machine in the form of a manure spreader on the market which he believed was working successfully. It cost about £40, but if several farmers bought one between them the cost would be a mere nothing compared with the advantage gained. In his district he thought Huguenot wheat would be worth trying for fodder. He had also tried rape. Rape seed was rather expensive; he had bought some from a firm in Adelaide and it had cost him nearly 1s. per pound. (A delegate—"The price is 35s. per hundredweight.") He would like to know if sorghum had any renovating effect on the soil.

Mr. Lowrie said his experience with sorghum was that the wheat sown afterwards suffered. He thought that was due to the exhaustion of moisture. He did not think growing sorghum would benefit the land to any extent.

Mr. G. Pengilly (Willunga) had found that the growth of green fodders resulted in a heavy increase in the yields from succeeding wheat crops. The effect of growing peas last year was distinctly noticeable in the crops at present.

Mr. A. Carmichael (Port Germein) desired to know whether it was advisable to cut off stubble, or whether it should be ploughed in.

Mr. Lowrie replied that if the land were to be used for peas, he would cut or burn off the stubble. But one should hesitate to burn off the stubble to put in a crop like rape. It was a pity to lose the humus. It would be better to cut and stack the stubble. If they ploughed in stubble in the North, the land would be far too open. He would not advise them to plough in the stubble in the Baroota country for the first year. It would pay better to

burn it off, and purchase nitrogenous manures, such as dried blood. The better course was to use more manure, and encourage the trefoil.

Mr. J. C. Jacobs (Angaston) desired to know whether nitrate of soda was injurious to land.

Mr. Lowrie stated that nitrate of soda was one of the means of encouraging the vigour of growth of plants. The effect was that the crop took more out of the land, because it was heavier. He would not use it in South Australia unless for the purpose of forcing something in the orchard or the garden. Dried blood was a better application to make.

A visitor desired to know the most advantageous time to feed off peas.

Professor Lowrie recommended allowing the peas to lie whilst there was plenty of other food available. They should be nearly ripe before the stock was put on to the crop, and it was not advisable to feed them off too early,

(To be continued.)

CEREAL HARVEST, 1912-13.

The Government Statist has collected preliminary reports from the collectors of statistics in the chief wheat districts of the State indicating the condition of the crops as at the 20th to the 25th September. From these reports a brief review has been compiled respecting the counties in each division of the State. The present reports indicate that the area sown for wheat will show a slight increase, and barley a good increase, and that a less area will probably be cut for hay. From a general review of the reports it would not be safe at this date to anticipate a better yield than last season, when the average was 9.25 bush., though if the areas are not visited by hot winds and the needed October rains fall and are well distributed a slightly better average yield is more than probable. He considers it too early in the season to venture upon a more definite forecast of the possible yield as so much depends upon the weather conditions to be experienced during this and next month. He will, however, issue a detailed forecast compiled from later and more complete particulars on the usual date, November 30th.

SUMMARY OF THE REPORTS AS TO THE PROSPECTS OF EACH DIVISION.

I. CENTRAL AND II. LOWER NORTH.—*Acres*.—Wheat and oats, slightly increased; barley, a large increase. *Prospective Yield*.—Favorable for a slightly better average than last season, and if good October rains fall still better.

III. UPPER NORTH.—*Acres and Prospective Yield*.—The area sown is much smaller, and an even worse average yield may be expected than last season.

IV. SOUTH-EASTERN.—*Acres*.—A large increase in the area sown is expected in wheat, barley, and oats. *Prospective Yield*.—Owing to the excellent prospects of the Pinnaroo areas the division may be expected to yield a good average.

V. WESTERN DIVISION.—*Acres and Prospective Yield*.—The area sown appears to be greater than last season, but the prospects are not nearly so good, except in county Flinders.

THE WHEAT MARKET.

The following table, giving the wheat crop of the principal countries in the world for the last three years, and an estimate, revised up to August 12th of the 1912 crop, is taken from *Broomhall's Corn Trade News* :—

PRINCIPAL COUNTRIES WHEAT CROP (IN QUARTERS OF 480LBS.).

TO ADVERTISERS.

The "Journal of Agriculture" has a circulation of over 6,000 Copies monthly amongst the Cultivators of the Soil in South Australia, and consequently is a valuable medium for advertising Farm and Orchard Supplies and Requisites.

Particulars as to charges for space on application to the Department of Agriculture, Adelaide.

DAIRY AND FARM PRODUCE MARKETS.

The General Manager of the Produce Export Department reports on October 1st—

BUTTER.

The supply of cream is steadily increasing, showing a very marked improvement on last month. There is a great demand for butter, the present prices being—Superfine, 1s. 0½d. per pound; pure creamery, 11½d. per pound.

A. W. Sandford & Co., Limited, report on October 1st—

BUTTER.—The nice rains experienced in the early part of September somewhat checked the increase in supplies of butter and cream, but towards the end of the month much heavier quantities came forward, and values showed a slight easing. Best factory and creamery, fresh in prints, sold at from 1s. to 1s. 1d.; choice separators and dairies, 10d. to 11d.; store and collectors, 9½d. to 9¾d. per lb.

EGGS.—Prices have remained stationary throughout the month and were considerably higher than ruled at the corresponding time last year. Heavy over-sea orders, coupled with extensive local trade, cleared all offering at 9½d. per dozen for hen, and duck 10d.

CHEESE.—Considering the cold weather very heavy business has been put through, both for local and export. Quotations—New make, for large to loaf, 7½d. to 8d. per lb.; matured 10½d. to 11½d. per lb.

BACON AND HAMs.—The high prices ruling have somewhat checked consumption, but as bacon stocks are light, values have not been affected. Best factory cured sides, 10d. to 10½d. per lb.; hams, 11d. to 1s. per lb.

HONEY.—The first of the new season's honey is now on the market, but so far only small lots have come to hand. These are finding ready buyers at 3½d. per lb. for prime clear extracted; second grades are slow of sale at 1½d. to 2d.; beeswax is very saleable at 1s. 3d.

ALMONDS.—Demand has been somewhat slow, owing to buyers having already secured their requirements, but kernels are in good request. Brandis are selling at 5½d.; mixed soft shells, 5d.; kernels, 1s. 3d. per lb.

LIVE POULTRY.—The catalogues during September have not been nearly equal to trade requirements, consequently buyers have had to bid keenly for all offering. Good table roosters realised 3s. 6d. to 4s. each; hens and cockerels, 2s. 6d. to 3s.; ducks, 3s. to 3s. 6d.; geese, 4s. to 5s.; pigeons, 8d. to 9d.; turkeys, 8d. to 11d. per lb. live weight for fair to prime table sorts.

CARCASS MEAT.—Brisk business has been experienced with very tall rates ruling, owing to the scarcity of the live hog. Bright handy size shop porkers brought 6½d. to 7d. per lb.; good baconers, 6d. to 6½d.; heavy and light sorts, 3d. to 4d.; nice dairy veal, 3d. to 3½d.; medium quality, 1½d. to 2d.

POTATOES AND ONIONS.—There is no alteration to report in the potato and onion markets, the high prices checking consumption, but as there is a decided shortage no lowering is anticipated. Present quotations—Potatoes, £10 10s. to £11 per ton on trucks, Gambier; onions, £14 to £21 per ton on trucks, Gambier.

REPORTS OF CONGRESS.

As it would involve much repetition to print reports of delegates concerning Congress, these will only be published if discussion takes place which is likely to be of interest and value to other readers. Other reports will be classed as formal if this is the only business dealt with.—[ED.]

ADVISORY BOARD OF AGRICULTURE.

Dates of Meetings—

November 13th, December 11th,

THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the department for fuller particulars concerning the work of this institution.

REPORTS OF BUREAU MEETINGS.

Edited by GEORGE G. NICHOLLS, Secretary Advisory Board of Agriculture.

UPPER-NORTH DISTRICT.

(PETERSBURG AND NORTHWARD)

Amyton, August 27.

(Average annual rainfall, 11½ in.)

PRESENT.—Messrs. T. O'Donoghue (chair), S. Thomas, R. Brown, D. V. Aitkin, T. Ward, H. K. Gum, A. Crisp (Hon. Sec.), and one visitor.

CULTIVATION OF THE SOIL.—The following paper on this subject was contributed by Mr. S. Thomas:—"On the cultivation of the soil chiefly depends the success or failure of the season's crop. The object of cultivation is threefold, viz., (a) conservation of soil moisture, (b) destruction of weeds, and (c) the improvement of the soil. The most important problem in this district is how to make the surplus rains of the wet seasons help us out in a dry season. When we have solved this difficulty our troubles will be very materially lightened. The most important factor in attaining this is to start fallowing after the first rain after harvest operations. Our annual rainfall here is 12 in., and if we want the best results we will not be content to start fallowing after the greater part of it has fallen and run to waste, as is the case if we delay fallowing until after seeding is over, as that means that two-thirds of the year's rainfall is lost to the land. The position is this, that rain that falls on unploughed land will not improve that land at all. As an instance in proof of this: I fallowed some land many years ago a few days before a heavy fall of rain and when the land was dry, and ploughed some near it a few days after the rain, while it was still fairly moist and it turned over nicely. The first, that which was ploughed dry, yielded more than double the crop of that ploughed later while moist, proving conclusively that the rain that falls previously to ploughing does not benefit the soil to any appreciable extent, and whether land is ploughed when moist or dry is of less importance than that it should be ploughed early. Before the advent of the drill and manure, when most of us were finished seeding by the middle of April, it was permissible to start fallowing as soon as seeding operations were over; but now, when seeding is continued right through June, this is altogether too late. If we do not start until late in the season the first month may prove too wet; then perhaps we get a good fortnight's work in; then it is too dry, and the season is gone before we have done one half of that which we intended, as was evidenced in the numerous unfinished paddocks last year in this district. This year I started fallowing fairly early; one team was put on fallowing while the other was working the land preparatory to seeding. It is by far the best plan to get most of the fallowing done in the autumn or early winter, so that we have the land open to receive all or nearly all of the winter's rains. Land ploughed in March, April, and May this year has had bin. of rain on it since it was ploughed. This was lost to land ploughed late in August or September, and the former is therefore fortified against a dry spell to such an extent that is quite impossible with any land that may be ploughed later. We need to remember that land must first receive the rain that falls before we can work it beneficially to retain the moisture. If we fallow too late our trouble in working land to retain the moisture that never entered the soil is wasted. Further, the working of the land to kill weeds will need to be done late in the season, and it is apt to prove injurious to the soil on account of its extreme dryness. I prefer leaving the fallow rough and open through

the wettest part of the winter, say, until the end of July, as the more surface exposed to the air, warmth, and sunlight the better the results. By the end of July all fallowing should be finished, leaving the team free to work the fallow in order to retain the moisture in the soil. Harrowing should be first done in the same direction as the land is ploughed, and afterwards across. This will break the land down fairly level and firmly, and destroy most of the weeds, especially if scarifier harrows are used. If found necessary I would use the skim plough to destroy weeds. If fallowed early land can be ploughed deeper with benefit, but 4in. on the clayey soils and a little shallower on the light soils is usually sufficient. Work the fallow after every rain right through the summer, except perhaps in the harvest season." In discussing the paper Mr. Brown disagreed with the practice of ploughing the ground when dry. The Hon. Secretary would scarify the land to be fallowed before seeding instead of ploughing it. This would encourage a quicker germination of weeds and rubbish after rain, and the land would plough up in a nice mellow condition. Members agreed that it was advisable to break the surface of the soil in order to allow it taking in moisture.

Arden Vale and Wyacca, August 29.

(Average annual rainfall, 16in.)

PRESENT.—Messrs. J. H. Willis (chair), J. Absalom, W. Fricker, H. Liebich, M. Eckert, C. Starr, E. W., J., and T. Klingberg, R. Paynter, O. E. Hannemann (Hon. Sec.), and five visitors.

RABBIT-PROOF FENCES.—The Chairman dealt with the subject of the construction of wire netting fences over waterways. The best plan was to put strong strainers above the high-water mark on either side of the course, strut them securely, strain the wires on each side, and then staple on the netting. A wire should be run through the tops of the strainers across the creek, well up out of the floodwaters, and to this two widths of netting laced together should be hung. Care should be taken that no gap was left between the netting and the strainers. Not more than 6in. of the netting should lie in the bed of the creek with the flap down stream. On to this stones should be placed. After the floodwaters had passed all that was necessary was to replace the stones and adjust the netting.

HAY.—Mr. M. Eckert contributed a paper, in which he recommended farmers to cut more of their crops for hay than had been done in the past. Wheat intended for hay should be an early variety that would provide a good color in the chaff. Dart's Imperial was a good sort to sow on clean land, but as it was a slow grower the wild oats got ahead of it where the land was at all dirty. Where it was intended to sell chaff the farmer was advised to use engine power for his chaffcutter. A 5-h.p. engine would supply the necessary strength.

Morchard, August 31.

(Average annual rainfall, 11½in.)

PRESENT.—Messrs. Scriven (chair), W. Toop, G. O. Rafferty, E. J. Kitto, R. Jasper, W. A. Toop, H. Kupke, J. Waters, E. D. Kirkland, H. A. Toop, W. Munro, B. S. McCallum (Hon. Sec.), and one visitor.

MARKETING WHEAT.—In a paper dealing with this subject Mr. Rafferty drew attention to the fact that the wheatgrower was not receiving satisfactory treatment at the hands of the merchants. He expressed the view that the Government should undertake the marketing of this product. The prices which the farmer had to pay for bran and pollard were crippling the dairying, pig-raising, and poultry industries. These, considering the price which the farmer secured for his grain, should be much lower.

Mount Remarkable, September 6.

(Average annual rainfall, 21in.)

PRESENT.—Messrs. L. A. Bauer (chair), J. McIntosh, T. H. Casley, N. S. Giles, M. G. Giles, E. M. Willington, E. B. Andrews, and H. H. Davies (Hon. Sec.).

ANNUAL REPORT.—The annual report of the operations of the Branch during the year just closed was read by the Hon. Secretary. Mention was made of the success which had attended the efforts of the Bureau in bringing together delegates from different parts

of the district with the idea of discussing the proposed water schemes in connection with the Willochra. An effort has also been made by members to form a vigilance committee, with a view to improving the township.

Wepowie, August 27.

(Average annual rainfall, 12in.)

PRESENT.—Messrs. J. Orrock (chair), G. Goss, C. Knauerhase, J. Chrystall, M. M. Irvine, T. F. Orrock (Hon. Sec.).

THE SHOP ON THE FARM.—Mr. J. Orrock read a paper on this subject, in which he stated that with a well-equipped blacksmith's shop on the homestead time and money could be saved. It often required longer to take work to the local blacksmith than it did for the farmer to do it himself. A good forge, an anvil, tongs, hammer, vice, drilling machine, punches, and hot and cold chisels were practically all the tools necessary. The tines or teeth of an old horseshoe made excellent shoes. He had forged shoes from the springs of an old buggy, and they had lasted almost twice as long as iron. A farmer could also make split links in his shop. When welding links in old chains, the ends should be made thinner in order to fit the worn links. With stocks and dies bolts of the length required could be made. In the discussion which followed members agreed that much time and expense could be saved if a blacksmith's shop and a few tools were on the farm.

Willowie, August 27.

PRESENT.—Messrs. T. Hawke (chair), E. S. Bristow, A. R. Wilkin, F. Richter, L. Hughes, D. L. S., and J. McCallum, E. J. Kentish, A. W. Howard, S. C. Greig, W. P. Foulis (Hon. Sec.), and one visitor.

FARM TOOLS.—Mr. E. J. Kentish contributed the following paper on this subject:—"The man on the land is primarily a farmer, and has to do with tilling the land, tending and rearing stock of all descriptions. These occupations make such demands on his time that it frequently happens that it is best for him to leave work for tradesmen as much as possible. Often, however, the trouble of going to the shop for his needs, together with the expense, makes it advisable that many things should be done at home. Some think a forge a very necessary part of a farmer's outfit. My opinion is that it is not of much value unless there are tools at hand and reasonable accommodation is available. The expenditure involved will only be justified where the individual need requires it. I have found it very necessary on occasions to shoe horses; not that it is cheaper, but it sometimes happens when ploughing or working a stony paddock that a horse will show tender. The animal can be shod at home twice over in the time that it would take in going to and from the shop. When horses are usually worked barefooted it is better not to burn the hoof much, as it stands better when the shoe is removed if it has been put on cold. Some good tools for hoof-cutting and shoeing should be on most farms. A strong vice is a necessary tool, and a hand-screwing apparatus is very useful. I have found the hand drill a simple device for boring iron. Every farmer needs a good supply of wrenches and spanners of all sizes, and a strong grip wrench or pipe wrench is a very necessary part of his outfit. Wood and iron chisels are in considerable demand, and should be kept in good order. Wood rasps and files may be needed at any time. So also with bits of all sizes from $\frac{1}{4}$ in. up to 1 in. These should be at hand at a moment's notice. Tools should be kept in order. Where different tools are constantly being taken to the field for use they are apt to be lost." In discussing the subject, Mr. S. McCallum said the farmer should procure a few tools for his workshop, which Mr. L. Hughes thought should be situated handy to the dwelling-house. Mr. T. Hawke thought the farmer should devote all his time to the land. In the majority of cases where he tried to effect repairs that should be in the hands of the tradesman, the result was far from satisfactory. Members generally agreed that it was advisable for every farmer to keep a stock of useful tools, but it was undesirable to attempt repairs that required the attention of a skilled tradesman.

FENCING.—Mr. E. J. Kentish dealt with this subject in a paper as follows:—"In this and many other parts of this State posts are very scarce, and carriage is a big item where wooden posts have to be carted 15 or 20 miles. If all iron posts are used the fence is not so firm. I have constructed a fence of the following dimensions, and would recommend it as serviceable, cheap, and easily constructed for sheep and great stock:—Place one large split red gum or box post to the chain with three T iron posts and four droppers

between, making in all eight supports to the chain. Put strainers 7ohns. apart, 2ft. 6in. in the ground for line strainers, 3ft. in the ground for corner and gate posts, and 18in. to 20in. for ordinary posts. The first wire should be 7½in. from the ground, the next three 5½in. apart, and the remainder 6in., 8in., and 10in. respectively. For the top wire use 12 x 3 barb, then one plain wire and one 14 x 3 barb, making two barbs and five plain wires. It is advisable to put in an extra wire and make the fence high enough to resist great cattle, and to make a good sheep-proof fence. It cannot be more than 3ft. 3in. or 3ft. 6in. in height with six wires. This is not high enough for cattle, as they jump over and knock the fence about, and young horses will gallop over it, and in a good many cases ruin themselves. If a fence is 4ft. high they will not get their heads over so easily. Posts well strained and rammed do not require to be buried to any great depth." Mr. Kentish, in discussing the question, said 4ft. was unnecessarily high for fencing. Iron posts would be found cheaper than wooden. Mr. Howard mentioned that where there was a danger of fire the use of iron posts was advisable. Mr. J. McCallum preferred the bottom wire of the fence placed 6in. above the ground, a plain wire 7in. higher, and then two barbed wires 10in. apart with the bottom one 8in. above the next directly below. Mr. S. McCallum said that where the droppers of a fence were fixed or tied the wires remained very much tighter. Mr. Hawke thought trouble would be experienced with sheep crawling under if the bottom wire were put more than 6in. above the ground. Wooden posts should always be charred, as this preserved them against the ravages of white ants. Mr. L. McCallum said that drift would soon accumulate and prevent sheep crawling under the fences. Half a chain was quite far enough apart for wooden posts, which could be protected from white ant by the application of tar.

Wilmington, August 28.

(Average annual rainfall, 17½in.)

PRESENT.—Messrs. J. Hannagan (chair), Litchfield, Noll, D. and S. George, Farrell, Hill, Slee, Forbes, Benier, Zimmermann, J., W., and G. Schuppan, A. R. and E. J. Gloede, and B. Jericho (Hon. Sec.).

WEEDS ON FALLOW.—Mr. E. J. Gloede read the following short paper on this subject:—
 "The destruction of weeds on fallow is best carried out when the soil is in a dry state, so that all disturbed plants die off. Early fallowing gives the farmer a chance to properly work his land, and the soil does not set so hard. Stinkwort is never so bad on early as on late fallow. For several years I have gone to much trouble to clear my paddocks of 'Three-corner Jack' and stinkwort. This year the latter got too strong a hold, as seeds were blown from places where nothing had been done to destroy this weed. Three-corner Jacks and couch grass seem hard to eradicate. I tried to destroy this grass by ploughing deep, but it spread worse than before. Although I picked the Three-corner Jacks where they grew, they seem to come up in the same places." In the discussion which followed, several members pointed out that stinkwort was worse on early than on late fallow. Mr. Gloede stated that sheep would sometimes feed on the leaves of Three-corner Jacks. The only method of eradicating them was to either hand-pick them or dig them out with hoes.

Wilmington, September 25.

(Average annual rainfall, 17½in.)

PRESENT.—Messrs. J. Hannagan (chair), D. George, Noll, J. Schuppan, Zimmermann, Hill, G. Schuppan, Forbes, Benier, Litchfield, A. R. Gloede, B. Jericho (Hon. Sec.).

SOUTH AUSTRALIAN WHEAT INDUSTRY.—The Hon. Secretary contributed a paper respecting wheat-growing in this State. He referred to the improvements that had been made in the selection of varieties, and stated that from a miller's point of view, while improvements had been made, the gluten content was still low as compared with the grain from other parts of the world. He urged the necessity for careful and constant experiment on the part of farmers, that they might secure varieties best suited to the conditions prevailing in their district. He favored the building of railways in advance of the settlement of the land. The aim should be to grow the best quality of grain with due consideration to yielding capacity. There was plenty of room for expansion in the production of wheat, and farmers could, with confidence, take the fullest advantage of the favorable climatic and other conditions, in the assurance that there would always be a market for their produce.

Wirrabara, August 24.

(Average annual rainfall, 30in.)

PRESENT.—Messrs. E. J. Stevens (chair), A. E. Stott, G. Hollett, F. T. Jettner, P. J. Curnow, P. R. Hoskins, P. Lawson, H. Lawson, C. Hollett, W. H. Stevens, J. F. Pitman, W. Marner, E. Hollett, and A. R. Woodlands (Hon. Sec.).

FARM MANAGEMENT.—Mr. J. F. Jettner read the following paper:—"Good management on the farm is of vital importance, for the greater number of failures may be traced to bad management. Farming, as a business, requires much forethought and close personal application. Therefore it is necessary that every farmer should make a special study of his farm, and everything that is needful thereon. In the first place it is important to be careful in all financial ventures. One needs to go carefully into the cost of implements, &c., required each season, and then consider what it is possible to do without. Buy first class implements, for waste, bad quality of work, and lost time are the chief leakages which have to be met. The question of labor is very important. Always give preference to a competent hand, and at the same time remember he is worth the highest wages circumstances will permit. When improvements are required the aim should be to construct them to serve as many purposes as possible, and at the same time convenience and comfort should not be neglected. The material used should be durable. Implements should be kept under cover. This will add to their length of service. A liberal allowance of paint, particularly with regard to woodwork, is necessary. Farm horses deserve the best attention and should be kept in good condition on plenty of good chaffed hay. It is well to hold a good stack of hay in reserve. The preparation of the land for cropping is of great importance. If it is not well fallowed, cultivated, and harrowed, and all weeds kept down, the chances are against a good result at harvest time. The urgency of dispatch of all work with regard to fallowing, seeding, and harvesting accounts for the difference between success and failure. Sheep, cattle, pigs, and poultry, if properly managed, will add materially to the returns of the farm. Wool, lambs, and mutton can only be produced successfully where experience and careful judgment prevail. The safest line to follow is to hold plenty of feed in reserve. The best time to reduce the flock is in August, in order to allow the grass to seed. Re-stock at the end of the summer. A few lambs of good quality are worth more than double their number of miserable stunted weeds. Quality means everything. Cows should only be kept for the supply of the farm. Poultry in limited numbers only should be kept. The water supply should not be neglected, and, if possible, there should be water in every paddock. Wells are preferable. It is important that stock have free access to water if they are to keep their condition during the summer months. The time lost driving them to water and the destruction of feed is a serious loss that is not always fully recognised. There are many difficulties that the most thoughtful and careful farmer has to contend with, but at the same time his aim should be to make his occupation as pleasant as possible." During the discussion which followed the reading of the paper, it was mentioned that a mixture of kerosine and tar in equal parts made an excellent paint for ironwork. Wooden wheels were best treated with boiled linseed oil.

MIDDLE-NORTH DISTRICT.

(PETERSBURG TO FARRELL'S FLAT.)

Crystal Brook, August 24.

(Average annual rainfall, 15in.)

PRESENT.—Messrs. M. P. Pavy (chair), W. J. Venning, A. Miell, G. Miell, R. R. Shaw, B. Flavell, G. A. Solomon, J. Pridham, J. Teakle, R. Heaslip, W. Hutchison, A. E. S. Clarke, W. Carmichael, A. E. Cooke, G. Davidson, B. Weston, J. H. Shearer, J. Duffield, A. MacDonald, W. W. Robinson (Hon. Sec.), and two visitors.

FRICTION.—Mr. Shaw read the following paper:—"No machinery, however delicately made, is entirely frictionless where there are moving parts. This is reduced to a certain extent by applying a coat of oil between the two bearing surfaces, which prevents the metals coming into contact. Undue or excess of friction means loss of power. Farming implements that have quickly revolving parts, such as harvesters and binders, should

have their spindle bearings in proper alignment, otherwise there will be friction requiring a greater draught, also a greater wear on the bearings. It is a great mistake for farmers to use so-called cheap lubricating oils for their implements; they are dear at any price, as they gum up and play havoc with the bearings, cause a greater draught on the horses, and a more frequent visit to the machinery depot for spare parts. When using these implements it will be found advantageous to go over all the bearings and moving parts every few days with kerosine instead of oil. This will clean the bearings and wash out the old oil; then shortly after give a supply of fresh lubricating oil. The difference in draught will be surprising; but do not run too long on the kerosine before oiling all round. Farmers would find it a great saving if they made themselves conversant with the use of antifriction metal. It goes under several names, such as white and Babbitts metal. By its use a lot of old worn bearings can be run and made as good, and very often better than when new. It is fairly easy to run the bearings, and full instructions as to its use can be obtained from the agents. Friction is caused by vehicle wheels not being set in alignment—mostly spoken of as 'axles not being properly set.' There is a great difference in the running of vehicles. Some wagons will take the same load with six horses as others will take with seven horses; and yet, to the casual observer, the two wagons are alike and built by the same maker. How rare it is for one to go over a farm from the entrance gate to the furthest paddock and find all gates properly hung. In a great many cases the fastening of the entrance gate is most complicated, frequently only to be removed with the loss of a little skin. It is necessary to lift the end of the so-called gate to prevent it ploughing out a deeper semicircular furrow in the soil. Division gates on such a farm are mostly composed of three barbed wires and a few mallee sticks, causing more loss of time than would be entailed in the manufacture of a decent gate. The entrance gate to a farm is a fair index to the owner's farming methods. Another undesirable friction is that which causes horses sore shoulders. I admit that in some cases it is next to impossible to prevent this, as some horses are very thin-skinned, and others scald very easily; but if more care were taken there would be less trouble. Almost every farmer has his own special cure for this, but a well-fitting collar is the first thing to see to. The next is to keep it clean and ease any place that may be causing a sore. Bathe the shoulders night and morning with a mixture of common washing soda and water. The idea of one of the most progressive farmers that I know is to first get a collar that fits the horse, soak it in water, and while the collar is wet work the horse in it; being soft it will conform to the shape of the shoulders. After being allowed to dry thoroughly it is given two or three coats of good paint on the cheek side. This forms a smooth and almost frictionless surface, with the result that he rarely has a horse with a sore shoulder. There are some forms of friction that are indispensable on the farm, a few of them are the friction between driving belts and face of pulleys, the friction of strippers, harvesters, and binder driving wheels in contact with the ground, which is necessary for driving the machinery. It is also friction that causes a wire nail or spike to hold so tightly when driven into wood. Then again the friction caused by brakeblocks on vehicles and implements is very necessary. The friction of horses' feet on a hard metal road enables them to pull their loads. If the friction is reduced by a slippery road the hauling power is reduced also. In dealing with friction of another kind, viz., that between man and man and man and beast, I would like to say that sometimes we are apt to forget that farmers and farm laborers are only human and subject to human weaknesses. It takes a lot of the farmer's time to look after some men, as tools are left or thrown down where used and frequently lost. If there is a weak place in any tool or implement it does not take this man long to find it. I do not wish to convey the idea that all farm laborers are black sheep—far from it. So far as I have seen there is not a better class of contented, hard-working, and industrious men in the Commonwealth than the straightout farm laborer. On the other hand, the friction is not always caused by the hired hand, as occasionally a farmer looks on his man as of far less value than one of his beasts in the paddock, and treats him as such, continually nagging at him from morning till night; everything he does is wrong. This class of farmer, I am pleased to say, is the exception and not the rule, as the farm laborer of to-day receives treatment far different from that which he received some years ago. Speaking generally, he is better paid, fed, and housed, and this has a tendency to lessen friction between employer and employé. Friction between man and animal on the farm is, I am afraid, too prevalent. A short-tempered, cruel man has no place among stock. As one writer has put it very clearly—'A bad tempered man is seldom of much use among stock; animals soon get to discriminate between those who are cruel and those who are kind to them. They will do much more for their friends than their enemies.' The writer knows of a case in this district where two men started with a team each at a long fallowing on the same farm. One started with a team in low

condition, the other had one in good condition. When the work was finished the order was reversed, as the fat team was poor and the poor one fat, and yet the team that was poor at the start had more acres to its credit. The explanation is—the one was kind to his team and the other cruel; both teams were fed alike. Where there is friction between man and dairy cows the contents of the milking pail show it very quickly. Animals of all kinds appreciate a kind but firm owner." Mr. Venning, in discussing the question, said wooden gates were preferable on the farm, as when broken they were easier to mend. The dipping of collars in water was beneficial where a heavy load was to be pulled, but with ploughing not much benefit was derived from the practice. Mr. Heaslip said sore shoulders frequently originated with lumps or boils, even if the greatest care were taken by the farmer. Mr. Teakle was of the opinion that machinery was frequently discarded by farmers before it was thoroughly worn out. Mr. Carmichael believed boils and blisters on horses' shoulders were due to the animals blood being out of order. Where collars caused bruises through becoming lumpy the trouble could be removed by the use of an awl.

Leighton.

PRESENT.—Messrs. T. Goodridge (chair), W. Gollett, S. Williams, J. Goodridge, J. McDonnold, J. Earle, W. Bailey, G. Bailey, W. Williams, D. Keynes, R. McWaters, R. Fairchild, A. E. McWaters (Hon. Sec.), and two visitors.

THE ELDERBERRY.—Mr. T. Goodridge read the following paper:—"There are two varieties of this tree, the black-fruited and the green-fruited, and, in addition, a garden variety, which is variegated, with white markings on the foliage. The tree is ornamental, with broad cymes of blossom and pale-green foliage, and in the autumn it carries masses of black fruit, contrasting well with the foliage. As a fruit-yielding plant it is not to be despised. It gives the popular elderberry wine, which, when taken warm or mulled with spices, is a most excellent remedy for colds and a composing draught on going to bed. The blossoms are used for distilling elder flower water, which is a cooling application in cases of inflammation of the face and in the case of attacks of erysipelas. An infusion of the leaves is fatal to various forms of insect life, and is used, when diluted, to destroy thrips, aphides, and red spider on plants too delicate to stand Gishurst and other solutions. The foliage is not eaten by cattle, and if laid in a green state in rooms or granaries frequented by mice it will drive them away. A few branches stuck about the harness of draught horses will greatly mitigate the plague of flies during summer. The elders are propagated by cuttings, which root freely in any ordinary soil."

Mount Bryan East, August 24.

(Average annual rainfall, 15½ in.)

PRESENT.—Messrs. W. Quinn (chair), Gare, B. and W. Dunstan, T. Quinn, Hughes, F. Thomas, B. and L. Webber, and R. Thomas (Hon. Sec.).

EMASCULATING COLTS.—Mr. B. Dunstan read the following short paper on this subject:—"Before the operation of castration is commenced, pour a small quantity of oil into the animal's sheath. Grasp the neck of the scrotum firmly with the left hand, and make a slow but bold incision, and let out the testicle, leaving it suspended by the artery, after severing the muscular tissues. With the right hand the emasculator should be placed on the artery and the handles pressed tightly together for a period of from 20 seconds to 30 seconds. At the completion of the operation the wound should be dressed with carbolic oil. The emasculators are responsible for less swelling than is experienced when the clamps and searing irons are used."

Port Broughton, August 23.

(Average annual rainfall, 14 in.)

PRESENT.—Messrs. Pattingale (chair), Whittaker, Barclay, Hill, Pattingale, jun., Hoar, Harford, Fletcher (Hon. Sec.), and one visitor.

FOXES.—Mr. Pattingale mentioned that success had attended efforts to poison foxes by using baits consisting of birds, such as pigeons. Members agreed that the foxes had done a great deal of good in the district by clearing out rabbits,

Port Broughton, September 20.

(Average annual rainfall, 14in.)

PRESENT.—Messrs. G. E. Pattingale (chair), Whittaker (two), Excell, T. E. Pattingale, Barclay, Harford, and Fletcher (Hon. Sec.).

TICK AND LICE ON SHEEP.—Mr. Barclay drew attention to the prevalence of this trouble amongst flocks in neighboring districts, and advised members to dip their sheep.

SALT FOR HORSES.—Members generally agreed that it was advisable to provide salt for horses in the shape of a lick. When it was given with the feed there was a danger of the animal receiving too much.

Port Germein, August 31.

(Average annual rainfall, 12in.)

PRESENT.—Messrs. Carmichael (chair), Head, Deer, Glasson, Teasdale, Stone, Hillam, Hacket, Crittenden, Stock (Hon. Sec.).

STABLE MANURE AND FALLOWING.—Mr. Deer read the following paper on this subject :—"In many places stable manure is wasted, not because farmers do not realise that it is of value, but because of the trouble and time required to place it where it will prove useful. Fertilisers, such as superphosphate, are much more quickly applied to the land, and results obtained are beneficial, but the use of stable manure in addition to other fertilisers is to be recommended. I would spread it on the land to be fallowed, heavily on poor land, and lightly on heavy soil. If it is impossible to spread the manure before fallowing, it should be put on the fallow and worked in. Where I have carried this out the results obtained have amply justified the trouble incurred. Substance cannot with impunity be taken from the land without an equivalent is returned to it, and stable manure provides the properties that the land requires. It also keeps the land more open. The object of fallowing is to clean the land, to conserve moisture, and to keep the soil open in order that the air may have free access to it and supply a certain quantity of nitrogen. The time to fallow is the most important point. When land commences to drift, it appears impossible to stop it. If it is allowed to become "drifty," the fine particles disappear, and a coarse gravel is left, and the value of the yield decreases. Drifting is frequently caused through too large an area being worked. Narrow strips of crop should be put in, and pieces of fallow left between the strips. The prevailing winds should be studied, and the strips arranged in order that they will afford the greatest amount of shelter. When cutting wheaten hay, it is not only the question of weight, but the quality, that should be considered. Horses do better on hay cut when the flower is just dropping. Grain should be added if necessary. Hay is not so easily digested when in the dough state, and horses are liable to suffer from the various complaints which have indigestion as a foundation." In the discussion which followed Mr. Crittenden considered that cultivating in strips was not profitable, as much feed would be lost. He considered drift in sandy soil beneficial, as it checked the growth of weeds. Mr. Carmichael agreed with opinions of the writer.

Port Pirie, September 7.

(Average annual rainfall, 12½in.)

PRESENT.—Messrs. E. B. Welch (chair), T. Johns, W. Munday, F. A. Johns, J. Greig, W. L. McEwin, H. G. Hawkins, C. E. Birks, A. M. Lawrie, H. Lawrie, T. B. Jose, A. Bond, W. R. Wright (Hon. Sec.), and 20 visitors.

LOUSY SHEEP.—The Chief Inspector of Stock, Mr. T. H. Williams, addressed the meeting on this subject. He stated that the only way in which the pest could be exterminated was by dipping all sheep, which could be done at a cost of about 1d. per head. Non-poisonous and tar preparation dips were useless, as they only cleared the lice away for about a month, then the disease became as bad as ever. It was not desirable to dip immediately after shearing, this was best done a month or six weeks later. Farmers should co-operate in building dips, thus saving a good deal of expense. If they neglected to stamp out the disease it would soon get a very strong hold, and severe loss might result to sheepowners. Dipping improved the wool. A flock free from disease would not become infected unless it came into actual contact with lousy sheep. Owners of lousy sheep were liable to a heavy penalty for exposing them for sale in a public saleyard. The law also provided that such sheep should not be travelled along a public road, or removed from the pasture on which the animals were when found to be infected. It was not the wish of the department to prosecute, but if owners persisted in being careless about the matter, the law would have to be enforced,

Whyte-Yarcowie, August 24.

(Average annual rainfall, 13½ in.)

PRESENT.—Messrs. G. F. Jenkins (chair), Faulkner, McLeod, Lock, M. Walsh, J. R. G. D., and W. Mudge, A. Mitchell, Wittwer, McGregor, Robinson, E. J. and F. Pearce (Hon. Sec.), and one visitor.

HORSE DENTISTRY.—Mr. G. McGregor exhibited a skeleton of a horse's head, and drew attention to the fact that the two back grinders of the top jaw had cut their way into the corresponding teeth in the bottom jaw. The former were quite ½ in. longer than they should have been normally, and it was suggested that the death of the horse through starvation was probably caused in this way. Mr. McGregor said the bottom teeth must have been softer than those in the top jaw, and he advised the cutting of teeth in similar condition with a pair of dental snips. There was no danger of the horse swallowing the pieces of tooth cut off if the animal were operated on when standing up, and the pieces were removed before the gag was taken out of its mouth. Members generally were of the opinion that it was advisable to examine horses' teeth regularly, but unless the animal were suffering on account of abnormalities it was advisable to leave the teeth alone.

LOWER-NORTH DISTRICT.

(ADELAIDE TO FARRELL'S FLAT.)

Friedrichswalde, September 21.

PRESENT.—Messrs. Goodfellow (chair), J. and F. Heintze, F. W. and E. Duldig, F. W. Schultz, T. Pfitzner, Coombe (Hon. Sec.), and seven visitors.

HARROWING GROWING CROPS.—The Hon. Secretary read the following paper on this subject:—"The system of harrowing growing crops has been practised in South Australia for a number of years, but it is only recently that it has become in any way general. The subject merits far more consideration from agriculturists than it has received, because of the benefits which the wheat plant receives from its practice. One of the chief objections is that it destroys so many wheat plants. Let us suppose for a moment that it does so, then the remainder of the plants benefit to an extent which easily compensates for the loss. Another aspect of the destruction by harrowing is that farmers who are opposed to the system very often lose more through careless and faulty pickling of the seed, but as they cannot actually see this loss, they do not realise it. The benefits of harrowing are numerous, but chief among them is the benefit to the soil, the destruction of weeds, and the checking of the upward growth of the plant. Harrowing the crop after it is out of the ground will help to conserve the moisture. For this reason it should be done after a rain. The loss of moisture by evaporation is greater than most people suppose, and any operation which tends to lessen that evaporation must certainly benefit the crop. By breaking up the surface crust evaporation is reduced considerably, and this is accomplished when harrowing is practised. The more frequently the soil is worked the more moisture is conserved. Then, in heavy land, harrowing has the effect of breaking the clods, especially after a rain. As a general rule weeds are more easily destroyed than wheat. This is due to the fact that the roots of the weeds lie nearer to the surface than do those of the wheat plant. While some wheat plants are undoubtedly pulled up by harrowing, it will be the weak, sickly plants, which, as a matter of fact are better out of it altogether, as, if they ever came to maturity they would yield but a poor return. The conclusion that harrowing checks the upward growth of the wheat plant is arrived at by the admitted fact that a certain amount of wheat plants and weeds are destroyed, thus leaving more nourishment and moisture for the remainder. This additional sustenance permits the plants to throw out fresh 'stools,' and as a natural sequence, more profitable returns are secured. Feeding off crops is practised a good deal, but I do not think the benefits to the crop by this method are in any way comparable to those obtained from harrowing. The harrows should have sharp points on long, thin tines, and the harrowing to be most effective should be done immediately after a rain, and when the wheat plant is firmly rooted, and is from 4 in. to 6 in. high. This is certainly an inconvenient time, as

fallowing will be in full swing, but it will pay handsomely to leave the fallowing for a time, and harrow the crops. What I have written applies chiefly to wheat intended for grain, but for hay crops I would advocate harrowing first, and then, to level the surface, rolling. Those who do not believe in the system of harrowing growing crops have it in their power to experiment, on say an acre, or even half an acre of land under crop. Even should a loss result, indirectly the experimentalist would be the gainer, as his convictions would be strengthened by practical knowledge. However, I have not the slightest fear that a loss would result, provided the experiment were carried out in a proper manner."

Greenock, August 31.

PRESENT.—Messrs. A. Heinze (chair), J. Jungfer, J. C. Jaensch, A. Nitschke, B. Nitschke, F. W. Nitschke, H. Koch, F. G. Pfeiffer, O. Semmler, E. Geyer, J. G. Arnold, W. Roenfeldt, E. Roenfeldt, P. Kernich, T. Listner, W. Nenke.

PRGS.—Mr. R. Tümmel read the following paper:—"The breeding and management of pigs should be one of the most important agricultural interests in this State. To be successful, none but the best breeds should be allowed on the farm. The first requisite is good feeding from the time the animals are born until they are slaughtered. You can neither breed nor keep pigs profitably by starving or allowing them to shift for themselves; as elsewhere, so in stock-raising it holds true, that what costs little to acquire brings little at sale. Care and labor to secure the best will always pay the most. Many years ago there was a big demand for everything large in the way of pork, and many people turned their attention to the Tamworth breed, for the simple reason that big hams and big sides of bacon were fashionable; but to-day there is a decided distaste to large joints. Bearing this fact in mind, I can thoroughly recommend the Berkshire. This breed, given proper attention, possesses wonderful powers of early maturing. The pigs are active and yet contented, and turn to good account the food they receive. The boar is the chief source through which the ordinary stock has to be improved, and as the offspring are likely to take his shape, it is most important that he should be well formed and sound. If he is high on the legs, thin in the forequarters, and narrow across the loins, it is certain that his stock cannot turn out well. The ribs should be well sprung from the backbone, the sides deep with thick flesh, and the flank full. A pig which is thin in the flank is not a good bacon pig, and the hams are generally badly developed. The sow should be the same shape as the boar, but there are points of maternity which should not be overlooked. Perhaps the most important is that having produced a family she should be able to support it. The minimum number of teats which a breeding sow should possess is 12. It is well to breed from a good-tempered sow, and one which has not shown signs of a desire to eat her young. The period of gestation is 16 weeks, and during this time she should be kept in good store condition and have plenty of exercise. Cereals are the most valuable feed for pigs; they are, however, apt to be too heating if they form the whole diet. It is a good plan to feed green barley or, if possible, let the pigs graze on it, as the system is kept healthy. Thick, square pigs are best for killing at an early age. Such pigs, if well bred, are never lean. When the aim is to kill them as small porkers they should never be stinted for food. It must not be forgotten that the pig that is being well fed requires something to counteract the acidity of the stomach, and this can be best given in the shape of wood ashes and charcoal, a supply of which should always be provided in the fattening pens." In discussing the subject, Mr. J. C. Jaensch said large hams were not desired at shows, about 12lbs. to 14lbs. was quite large enough. The Berkshire and Essex were the best bacon pigs, being early maturing breeds. The feeding of pigs made a considerable difference to the lard. Some was found to be quite crumbly, and other soft and white. Copra cake had a good effect on the quality of the lard.

Nantawarra, August 22.

(Average annual rainfall, 15in.)

PRESENT.—Messrs. R. P. Uppill (chair), S. Sleep, J. Nicholls, F. J. Sutton, T. Dixon, A. F. Herbert, J. Sinclair, and G. L. Tucker.

SUPER.—A general discussion took place on the free-running qualities of super.; also on the strength and general qualities of the different brands on the market. Mr. Sleep mentioned that at one time super. was supplied at a very high water-soluble percentage, and was mixed with sand by the farmers themselves. He thought the results were equal

to those obtained at present. Members were of the opinion that, if the results proved as satisfactory, a great saving in freight and cartage would be effected by receiving their super. in such a manner.

SEEDING.—Mr. J. Nicholls, in opening a discussion on "The advisability of sowing before or after the rain," said there was only one course to pursue, and that was to wait for the rain. This season, owing to the lateness of the rain, was an exceptional one, and many farmers had put in their crops in a dry state. The crops this year might prove a very good object lesson to the observant farmer. His contention should not be judged by one year's result, however. If taken over a period, say, of 10 years, he had no doubt as to the ultimate result. Because a farmer had 400 acres of fallow it did not necessarily follow that he should crop it all in the one season. A smaller area drilled in at the right time, i.e., after the rain, would more than compensate, through the increased yield, for the waiting. If a farmer, through waiting for rain, were only able to sow 300 acres out of 400 acres of fallow, but obtained nearly as much wheat off the 300 acres as would have been secured from the 400 sown in a dry state, he was a distinct gainer. In addition to the saving of seed, manure, and labor, he would also have 100 acres of fallow left for the next year. Mr. Sutton had worked his fallow—which was only separated from Mr. Nicholls's by a road a chain wide—a great deal more, and had drilled in his crop in a dry state a month before Mr. Nicholls had drilled his in. The difference in the two crops was very great. Mr. Nicholls's crop was a beautiful healthy green while his own was yellow-looking and withered. He considered his crop 50 per cent. inferior to the other. Mr. Sleep had observed that the majority of the crops sown before the rain were very weedy, and thought the returns would be affected accordingly.

Northfield, September 3.

(Average annual rainfall, 19in.)

PRESENT.—Messrs. Dall (chair), Goldney, Roeger, Reynolds, Wright, Eastwood, and Mitchell (Hon. Sec.).

FARMING METHODS.—Mr. Dall read a paper as follows:—"Agriculturists to-day have advantages which our fathers and forefathers had not. At one time land had to be ploughed with a single-furrow plough which, after a time, was replaced by the double-furrow, and years after by the stump-jump plough. We now have ploughs of four to 12 furrows. This alone has assisted the farmer to a very great extent both in saving of labor and enabling him to get over the work so much more quickly. Agricultural field trials could be given more attention. These trials or shows are too scarce. If more were held, and especially in connection with the Bureau, I feel sure that our manufactures would be better advertised. I know there is a vast difference in opinion as to the class of horse most suitable for the farm. The medium draught is condemned by a large majority of farmers, but I favor the medium light-boned horse. It stands more work and does it more easily, besides being easier and cheaper to keep. I would strongly recommend farmers to try horses about the stamp of the Suffolk Punch type. Deep or shallow cultivation has a large scope for experiments, and in some places these are being carried out. It is recognised throughout that the cultivating process is far more difficult now than it was years ago. Fallowing is undoubtedly the heaviest part of farm work. The usual custom is to plough 4in. to 5in deep, and in heavy land with a five-furrow plough it requires eight good horses. Here, I think, an experiment could be tried by ploughing, say, 3in. or even less, and I venture to say the same ground could be ploughed with six horses, thus saving two horses, which could be used for other work. With the cultivation that is given fallow land, I think the result would be as good. Experiments in wheat-growing are in an advanced stage, and should prove a boon to the farming community. Our own Government experimental works are a credit to those who carry them out, both with regard to treatment of varieties and the farming plots. I think the experimental work could be enlarged upon. If less wheat and manure would give as good results, why should we not economise? When drills first came in, the chief point in their favor was that there would be a big saving in seed. Before the drills, thin sowing was the general rule; to-day it is nothing less than a bushel of wheat, and up to 1½ bush. to 1½ bush. to the acre, with the result that there is more straw but less wheat. I would like to see an experiment of thinner sowing under the present method of farming carried out. Another trial which would prove an advantage to farmers is that of a threshing plant. Although it may mean a big outlay at first it would soon pay its way. If a few farmers were to co-operate the outlay would not seem so great. The plant could be fixed in some central place, and each farmer could have his crop treated as his turn

came. I feel sure better seed would be the result. It would give every farmer a chance to secure his own selected seed, which would be kept pure. The headed straw could be stacked, and if treated with salt would make good chaffed feed and an excellent standby, and also a saleable article for second-grade feed, especially if the crop were cut at the right time. Mixed farming is worthy of a trial. The benefits to be derived from sheep on the land alone would be great. Combined with the growing of fodder crops such as rape, kale, lucerne, peas, &c., it would give the farmer a good chance of keeping his sheep well, and he should, by careful selection, be able to raise fat lambs which should command the highest prices, especially where close to the markets. For our district I would suggest that good ewes be selected, and the best export lambs bred. Keep just that number that can be fed properly. When the lambs are disposed of, fatten the ewes and sell them or buy more according to the available feed. The putting down of ensilage is another item which should prove successful. Where hay is cut and thick sowing indulged in, one often has rank spots in the crop. If these were cut when standing or green and put into ensilage they would be better utilised than if left for hay. In districts like this ensilage is more economical than the system of carting out the sheaved hay to feed to cattle. It would pay farmers to put in a few acres of crop for the express purpose of making ensilage."

Saddleshworth, August 16.

(Average annual rainfall, 20in.)

PRESENT.—Messrs. P. Manning (chair), F. H. Kelly, W. Seales, W. Crawford, F. Snell, J. Plueckhahn, R. Rex, and F. Coleman (Hon. Sec.).

CUTTING WHEATEN HAY CROPS.—The article by Professor Perkins on the subject of the best time to cut wheat for hay, published in the June *Journal*, was discussed. Mr. Kelly was unconvinced that wheat cut in the green stage would weigh less than that cut later. Other members also thought the presence of more flag and a slightly bulkier straw would mean more sheaves to the acre, and would largely counteract the weight of each individual sheaf of the ripely cut hay. Members generally were in favor of cutting the hay with the idea of securing the best quality, and in this members supported the ideas of Professor Perkins. Wheats of the Medeah class, such as Le Huguenot and Indian Runner, should be cut as soon as the blossoming season was over.

Saddleshworth.

[CORRECTION.—In our last issue a paper on the care of harness was said to have been written by Mr. F. Coleman. This paper should have been credited to Mr. P. Manning, by whom it was written and read at the meeting.—ED.]

Salisbury, September 3.

PRESENT.—Messrs. E. V. Harvey (chair), J. Harvey, Bagster, Urlwin, McNicol, Sexton, Neal, James, Hooper, McIlashan, T. Judd, Hier, Goodall, Patterson, Sayers, Coker, Tate, A. G. Jenkins (Hon. Sec.).

THE EFFECT OF LIME ON SOIL.—Mr. E. Moss contributed the following paper:—"I do not apologise for quoting so copiously from Professor A. D. Hall's work on fertilisers and manures, because as a source of information on the subject he is regarded as one of the best authorities; and the subject is one of such vital importance to farmers in this district, with its heavy clay soils, that it seemed to me worth while to select and place before you such facts as would be of most value and most likely to be kept in mind. The references made by Hall to results from the use of lime apply mainly to experiments made in England, chiefly at Rothamsted Experimental Farm; but from experience in the use of lime in different forms in various parts of this State, we have no reason to believe that his conclusions will not apply with equal force here. At Renmark, and generally on the Murray settlements, gypsum is regularly used and looked upon as a necessity in bringing the soil into and keeping it in the best condition for cultivation, and the growth of fruit, &c. Gypsum is used because it is cheapest, being procurable a few miles from Renmark. The use of sea shell in this district has had such a marked effect in increasing the productiveness of the soil and in making the soil more amenable to cultivation that

a much more extended use of it can be safely recommended, and a few remarks bearing on this subject will not be out of place a little later on. 'There are several substances commonly used by farmers as manures, which produce desirable effects upon the crops, although they are not themselves plant foods and only act indirectly on the soil, either by making it more amenable to cultivation or by bringing into action the stored-up reserves in the soil. Such substances are lime, gypsum, salt, all of which contain elements present in the plant, though they also exist in the soil in quantities sufficient for the nutrition of the crop; they are valuable as soluble salts for their indirect effect in making when soluble other more important plant foods in the soil.' Hall says that it is not known when the value of lime was first discovered, but the uses of marl and lime were recognised among the Romans. He quotes from Pliny, who mentions different kinds of lime and their value both in the field and the garden: 'The regular use of some form of lime or chalk,' says Hall, 'was part of the accepted routine of farming as early as we possess any records of British agriculture, and among the manures it figures in all books of the sixteenth and seventeenth centuries. In fact, 'the black and the white,' dung and lime, were the only manures employed by the great mass of farmers until well into the nineteenth century. Lime itself, or quicklime, is obtained by the 'burning' of any form of calcium carbonate, which occurs as limestone (either pure in the mountain limestone of Derbyshire and North Yorkshire, or argillaceous in the Lias), as chalk, and even as shell sand, on the Cornish and other coasts. The so-called 'burning' consists in driving off by heat the carbonic acid contained in the calcium carbonate. The resulting lime, known sometimes as quicklime, stone lime, cob lime, lime shells, &c., combines with great readiness with water developing much heat and falling down into a fine powder, termed 'slaked lime,' and this slaked lime will then combine with the carbonic acid present in the atmosphere to reconstruct the original carbonate of lime. Thus when lime is applied to the soil it very rapidly becomes carbonate and the effects of 'liming' are really due to carbonate of lime. Since lime becomes calcium carbonate in the soil, obviously the same results would be obtained by applying the latter material; the main advantage in the use of lime lies in the very fine state of division into which it falls on slaking and the consequent good admixture with the soil that is effected.' Referring more directly to the practice of liming, Hall says: 'When the practice of liming was more general it was customary to apply very large amounts, 4 to 6 or 8 tons per acre at long intervals, but this is likely to act injuriously by causing too rapid oxidation in the soil at first, and the better plan is to put on 1 ton or so of ordinary lime every time the turnip crop comes round in rotation, or 5cwt. to 10cwt. of ground lime to each crop for which artificial manures are applied. A heavy dressing of lime is also supposed to affect the processes of nitrification detrimentally for some time after its application. Lime, chalk, or ground limestone, in whatever form it is used, should always be applied to the land as early in the winter as may be convenient, on arable land before ploughing. The question of whether lime is required as a regular part of the routine of farming on a given soil can only be decided by an analysis of the soil; any soil containing less than 1 per cent. of calcium carbonate will be benefited by liming, and when the percentage falls to $\frac{1}{2}$ per cent. lime becomes a necessity to enable the manures to exert their proper action. Many clays and sands are in this latter condition; and although the absence of lime may often be concluded from the appearance of the vegetation, every farmer ought to get a determination made of the amount of carbonate of lime in his soil, because the whole scheme of manuring should depend on whether the soil is properly supplied with a base. This is how Professor Hall says we may determine for ourselves whether or not lime is deficient in the soil: 'If a little soil, when covered with dilute hydrochloric acid shows no visible effervescence, the proportion of carbonate of lime must be below what is desirable for the healthy growth of vegetation. Nor must it be supposed that the use of artificial manures, such as superphosphate of lime, or bones, which are phosphate of lime, or gypsum which is sulphate of lime, will obviate the necessity of liming. Lime or its carbonate is needed in the soil to supply a free base, and in the compounds mentioned it is already saturated with a fixed acid; in fact, in superphosphate of lime there is an excess of acid, so that this fertiliser reduces the amount of carbonate of lime in the soil. Stone lime should be distributed in small heaps, covered with a little earth and left for a week or two to slake, under which conditions it will fall into a fine powder. The heaps are then broken down and thrown abroad before ploughing. The action of lime is partly physical, affecting the texture of the soil, and partly chemical, setting free the dormant reserves of plant food. On the strong soils the physical action of lime is most manifest; it acts by flocculating the finest clay particles, causing them to aggregate into temporarily larger units, and so making the soil effectively of coarser texture. The soil thus becomes less retentive of moisture; percolation is increased, making the limed land drier and warmer, so that

it admits of cultivation earlier in the spring and is far more friable when dry. In dry seasons the clay will crack less and the crop will keep on growing longer, because the improved texture of the soil admits of a better supply of subsoil water to the plant by surface tension. It is difficult to exaggerate the improvement that lime effects in the dryness and workability of strong soils, which, in many cases, would not be fit for arable cultivation had they not been so treated. . . . On the lighter soils—the sands and gravels—lime exerts a good effect by forming a weak cementing agent and increasing the cohesion of the particles. As a rule, however, it is not wise to apply quicklime in any quantities to very light open soils, because oxidation of the organic matter is pushed on too rapidly. Either chalk or marl, or some form of calcium carbonate should be used, or the quicklime should only be applied in small quantities. From the chemical side the great value of carbonate of lime in the soil lies in its power of maintaining the neutral reaction necessary to the development of those bacteria which oxidise the organic compounds in the soil to the state of plant food. In the absence of lime, organic matter by its decay gives rise to various acid bodies which may be grouped as humic acid, and the acidity thus produced inhibits the action of many of the valuable groups of bacteria, such as the azotobacter which fix nitrogen, and the nitrifying bacteria which convert ammonia into nitrates. It has been shown that in soils that are acid through the accumulation of humic acid, nitrification is at a standstill and bacterial life generally is repressed in favor of the growth of moulds and micro-fungi, which compete actively with the crop for the plant food in the soil. . . . It is on soils with a tendency to sourness that liming has such a good value, for in such cases dung or any other organic manure only tends to aggravate the evil. . . . It should also be noticed that the action of lime is slow, and is more manifest in the third and fourth year after its application than in the first and second. . . . But the nitrogenous compounds in the soil are not the only ones rendered more available by the presence of carbonate of lime; both phosphoric acid and potash are thereby kept or brought into a more soluble form. . . . A soil may contain considerable amounts of phosphoric acid, which in the absence of lime is combined with ferric oxide or alumina, so as to be in a highly insoluble condition. . . . Applications of lime or calcium carbonate are of great value on these soils, because they form a certain amount of calcium phosphate by interaction with the iron or aluminium phosphates, and so increase the proportion of phosphoric acid in the soil water. The action of lime upon the potash compounds in the soil is equally marked; as the soil water carries down the dissolved calcium bi-carbonate it attacks the zeolitic double silicates in the clay and a portion of their soluble bases, potash among them, changes place with the lime and comes into solution. Thus lime is precipitated and potash is found in the soil water. . . . Where potash had not been used prior to the application of lime on a certain plot at Rothamsted,' says Hall, 'there was little or no increase of yield, because there were no reserves of potash to be set free. That lime acts in this fashion may also be inferred from its beneficial effect upon clovers and other leguminous plants in a mixed herbage, or by the remarkable power of basic slag to promote the growth of white clover in a pasture where it was formerly dormant. Other phosphatic manures have often little effect in such cases, so that free lime in the basic slag, by liberating potash, is evidently as important a factor in the growth of clover as the phosphoric acid. If the basic slag is applied to a soil poor in potash it has little effect, and again after two or three applications to grass land it ceases to show its previous beneficial action upon the clover because the readily attackable potash in the soil has all been brought into solution, and a direct application of potash salts becomes necessary.' As this was probably the first district in South Australia to use sea shell as a fertiliser, some farmers here having applied it to their land as far back as 40 years ago, the awakening which is now taking place as to its value is interesting, and confirms what has long been held to be true by those farmers around here who have given it a trial. It will be remembered that it was regarded as incredible by some former heads of our Agricultural Department that shelling the land could have had the great results claimed for it here, when notice was attracted to the subject by some reference in the press; and it was then stated that whatever effects shell would produce would be due to the lime contained in it, and that the amount of lime applied in this way would be too small to do the good that it was said to have done. With this in mind it is interesting now to find that our present Director (Professor Lowrie) is urging the Government to secure the Spit at Kangaroo Island as a source of supply of shell for farmers, and he strongly recommends its use on farm lands. If shell has proved so beneficial here as is alleged by those who have tried it, the question will be asked, why has its use not become general amongst the farmers around where its beneficial effects will have become known, and where there is a source of supply so close at hand? This tardiness to take advantage of an opportunity to increase the fertility of the land at

comparatively small cost may be due more or less to two or three different causes. Farmers in the past were slow to adopt new methods. One of our largest farmers here, before following became as general as it is now, argued against it as a waste of one season's crop. Farmers are more progressive now, and ready to adopt anything that will promise better results. And again, I doubt if it was half believed that the shell did the good it was said to do; and we must not forget that this doubt has been encouraged by our chief agricultural authority in the past. And, last, though the shell is only a few miles away it meant the employment of a big team and a man to procure the shell and spread it on the land, and there always seems to be plenty for both horses and man to do on the farm nowadays. In the light of the proved benefits of lime generally, however (which benefits are calculated to follow its use in a special degree in our district), and the known good results which have been derived from the application of shell, it is worthy of serious consideration whether we are not losing in our returns every year by not more generally and systematically adopting shell as an important factor in the treatment of the land, and regarding labor connected therewith as part of the yearly routine of the farm. It is not possible that the whole farm could receive a shelling in one year. This, on an ordinary-sized farm might take five years, allowing for the work the time when the teams are not employed upon other necessary work upon the farm. It has been so consistently maintained by our farmers who have used shell, however, that its benefits are prolonged over very many years, and that they are very marked in some years, that the labor cost of one shelling seems about the most payable thing that a farmer could put his team at between the seasons; and he might even consider whether it would not pay better for a time to leave the carting of his hay to market to others while he gets a coat of shell on his land. Now to refer more particularly to the known benefits from the use of shell in this district, I remember being told more than 20 years ago by a farmer who was situated two or three miles west of this township, and who consequently was not very far from the source of the shell, that certain strips through his land had been shelled 15 years before and that these places then showed better results than the land which was untreated, the crops being higher, thicker, and greener. Doubtless influenced by this experience others have had portions of their land shelled, and in only one instance has it been said that it had not a most marked influence in improving both crop and pasture. The exception referred to seems to have been in connection with black land of a loose nature, which probably had a sufficient supply of lime, or was so open in its nature that shell might act quite detrimentally to it. Apart from this experience there seems to be no doubt as to the value of the shell in making the soil more workable and improving the returns from it. One told me recently that he could tell the land which had been shelled by the feel of it under his feet; that is, the shell was so effective in preventing the setting of the soil that it was sometimes noticeable by walking over it. On my own place I have always noticed a difference in the crop, and in the grass when there is no crop, on one portion of the land, and this part always shows a better crop very distinctly divided by a straight line across the paddock, and judging from the effects produced by shell in other instances and believing the former owner had some of his land shelled many years ago, I have always ascribed the difference noted to the shell. These will hardly be looked upon as scientific data, but a well-marked difference in a crop under stated conditions, if it is fairly consistently repeated, satisfies most farmers as to the value of the result of an experiment, and we find that those who have had most experience of the shelling of land are the strongest advocates of its use, and are showing their faith by getting more of it on to their land as opportunity offers. Professor Lowrie estimates the cost of shell, ground, from Kingseote at about 12s. 6d. per ton on truck, Port Adelaide. Delivered at Salisbury and spread on the land the price would be about 17s. 6d. per ton. The shell carted by the farmers' own teams from the St. Kilda swamps would probably average for different parts of the district about 4s. per ton. Allowing even a 50 per cent. superior value—which may not exist—to the Spit article, our local shell is apparently cheaper to use by 100 per cent. Probably our gardens would benefit by the use of shell, especially so where the soil is heavy. I had three samples of soil analysed by the Agricultural Department when Mr. Richardson was Acting Director, and the chief deficiency in the three was lime, and Mr. Richardson recommended lime to be used in some form, though he also thought superphosphate might be found beneficial. Probably shell would not prove of much benefit in our best alluvial soils, but by its more ready action upon the food elements in the soil quicklime would be likely to prove much more valuable in assisting the trees to develop a full crop to a state of perfection. I have used gypsum with good results as regards the physical condition of the soil, and I intend to try sea shell in places where the soil becomes compacted and quicklime where the trees bear heavy crops with small fruit."

Stockport, August 23.

(Average annual rainfall, 16in.)

PRESENT.—Messrs. F. Watts (chair), D. G. Stribling, C. Perry, S. Nairn, J. Smith, A. Rodgers, J. Connolley, T. Megaw, T. Howard, E. Weckert, G. Thomas, T. Higgins, R. Whitelaw, C. W. Cant, J. Murray (Hon. Sec.), and three visitors.

CO-OPERATIVE INSURANCE AMONGST FARMERS.—This subject was dealt with in a paper by Mr. Nairn, in which he pointed out the advantages that would accrue to the farmers if they adopted the system of co-operative insurance. A committee was appointed to draft out a scheme and bring the matter up at a future meeting of the Branch.

YORKE PENINSULA DISTRICT.

(TO BUTE.)

Arthurlton, August 28.

(Average annual rainfall, 16in.)

PRESENT.—Messrs. J. Welch (chair), M. Lomman, W. Short, A. Klein, J. Page, T. H. Howlett, J. Collier, R. and A. Burns, G. Bull, W. R. Stephenson (Hon. Sec.), and two visitors.

HOMESTEAD MEETING.—The meeting was held at the residence of Mr. G. Bull. The crops on the farm were inspected, and they gave promise of fair returns. One paddock, which was in wheat last year, had been sown in strips with barley, oats, and peas. The intention was to fallow it next year, and the following year to cross drill it with one variety of wheat in order to see the effect of the different crops on the succeeding wheat crop.

BEST WHEAT FOR HAY.—A discussion took place on this question. Members generally favored King's Early and Curly's Early. The heavy wheats mentioned were Majestic and Baroota Wonder. For length of straw Le Huguenot was best, but it was rather coarse and tough. Medeah was also a good hay wheat. The Hon. Secretary had drilled oats on stubble land, and had obtained most of his hay in that manner. Horses did best on oat feed, and it was grown more cheaply. An oat crop discouraged takeall.

BUNT.—It was generally thought that the pickling of oats in a solution of bluestone in hot water was more effective than when cold water was used.

Minlaton, August 23.

(Average annual rainfall, 17in.)

PRESENT.—Messrs. J. Martin (chair), R. O. Page, H. H. Evans, E. Correll, S. Vanstone, H. A. Chester, W. Bennett, S. F. Hoyle, J. W. Griffith, J. McKenzie (Hon. Sec.), and two visitors.

HARVESTING GRAIN.—Mr. S. Vanstone read the following paper on this subject:—“About 50 years ago the wheat grown in South Australia was acknowledged to be the best in the world, and it brought from 2d. to 3d. more per bushel than that grown in Victoria, to which State a great part of the wheat grown in this State was at the time exported. Now our wheat does not command a higher price than wheat grown in the sister States, and this is largely due to want of care in preparing for market. In the early days of this colony a great part of the wheat was cut with the sickle, threshed with the horse-power threshing machine, and usually put twice and sometimes three times through the winnower, the result being a clean sample of grain. Though no one would wish to go back to those primitive modes of agriculture, something should be done with our present up-to-date machinery in order that we may regain our good name. With little additional labor and extra expense the appearance and selling value of the wheat could be considerably enhanced. The harvester should not be used until the wheat is ripe. The neglect of this precaution has been the chief cause of the damage of wheat by weevil, which has been so prevalent since the introduction of the harvester. Wheat can be safely reaped with the tripper two or three days earlier than with the harvester, as the

dry chaff prevents the grain from packing too closely together and absorbs the moisture. For similar reasons damp wheat should not be put into the bags. Harvesters may often be seen at work when a light shower is falling. Sieves or screens should be cleaned often. It is impossible to obtain a clean sample when they are choked up. If there are a few bags that are not of a good sample they should be recleaned or fed to the fowls. The buyer's agent might pass them in, but it is not fair to the merchant, the agent, or to the farmer who makes a point of cleaning his wheat well. Unless some of it is very inferior, all the wheat is stacked together, and the slovenly farmer benefits by the careful man's extra work, as the prices are fixed upon the average sample. If by more attention to these small matters we can increase the value of our wheat by 1d. per bushel the gain to the State on a 20,000,000 bush. crop would be considerable." In the discussion which followed, members generally agreed with the paper, but thought there was not sufficient inducement for cleaning the wheat, as the easiest and quickest way of getting wheat to market generally paid best. The system of cleaning and marketing wheat was unsatisfactory, and the Branch would welcome any improvement, so that a better sample could be submitted to the various markets.

Minlaton, September 20.

(Average annual rainfall, 17in.)

PRESENT.—Messrs. C. Parsons (chair), R. O. Page, E. Correll, T. Giles, H. H. Evens, A. Washington, J. Boundy, A. D. McKenzie, J. McKenzie (Hon. Sec.), and one visitor.

FARM MANAGEMENT.—Mr. Evens read the following paper on this subject:—"Employ the most competent and industrious men obtainable, pay the best wages, but insist upon the laborer giving his best services in return. It is false economy to employ incompetent men and boys to do men's work simply because they work for less wages. Induce your men to start work early in the morning so that they may finish in good time at night. A man will complain and become dissatisfied much sooner at working late than he will at starting early. Do not put your men at disagreeable or unpleasant work such as cutting chaff on a windy day, or sewing bags, or stacking hay when the temperature is 110° in the shade. Do not wait until your chaffhouse is empty, but cut chaff when the weather is favorable. Insist on your men paying proper attention to the horses in regard to grooming and attending to their shoulders and regular feeding. Do not allow the practice of giving the horses enough feed when they come in from work in the evening to last until the next morning. The horses waste it if the manger is full, and it becomes stale and picked over, and they do not do so well as when they are fed up the last thing at night. Although it is the general practice to allow the horses to run loose in the stable and yard, I prefer that each horse should be tied up in its own stall, and its harness hung alongside. Otherwise there is always more or less fighting and kicking. The timid horse does not get its share of feed. They knock down the harness and tread on it. When you come to harness up, the horse has to be chased with the harness, often through a slushy yard. In the seeding time leave the paddock for dinner in order to reach the stable not later than noon, otherwise your men and horses work one and a half or two hours more in the forenoon. Procure all tools that are reasonably necessary upon the farm. When not in use keep each tool in its own particular place. Adhere to this rule rigidly yourself, and insist upon your employees doing likewise. The way to oil machinery is a 'little and often.' House your machinery direct from the field. Have your sheds of sufficient height to allow binders, harvesters, &c., to pass under freely. When you have finished with your machine do not leave it in the yard in the sun or rain and a menace to stock, but put it in the shed immediately. It has only to be done once. Also keep wagons, trollies, and drays under cover when not in use. Keep your machinery and vehicles in proper repair and paint them occasionally. In the event of a breakage, and you effect temporary repairs in the paddock, do not allow it to become a permanent repair, but take the first opportunity of fixing it up properly. In the case of a lost bolt a piece of wire will not make the parts so tight and rigid as another bolt would. Always keep a good supply of all sizes and lengths of bolts. They are very cheap, and you often lose the value of many bolts in time wasted looking for something to take its place. When you have finished with an article or machine borrowed from your neighbor, see that it is in as good order as when you borrowed it. Then return it to him promptly. Endeavor to keep your fences in good repair, especially the half adjoining your neighbor. It will prevent your stock trespassing and be an incentive to him to keep his half good too. After opening a fence to cart out stones, wheat, &c., fix up the opening properly.

Do not allow it to remain hitched up in a loose way for years. Do not erect new fences of less than six wires; with five wires the gauge is too wide for sheep, or the height is too low for great cattle. It is a mistake to spoil a good fence for the sake of an extra wire. In cultivating your paddocks keep the drill well away from the fences. If you drill close the swings often strike and bend the iron posts and stock are constantly pushing the fence by reaching after the crop. It is a good plan to cut around the crop with the binder. It saves knocking down the grain, gives you a fair start with the harvester, and allows you to keep the bags away from the fences without reshifting them. It has already cleared away the stubble for ploughing for burning, and allows of it being done before harvest, thus providing a cheap insurance against fire. When the time comes to burn the stubble, clear around any nice trees and protect them. They are worth the trouble, as they beautify the field and shade the stock. Should a tree, however, die from fire or age, remove it instead of cultivating around a dead log year after year. Let your neighbor know when you are going to burn and ask him to lend a hand. Then reciprocate. It is not nice for your neighbor to see smoke coming over the hill in his direction and not know whether it is by accident or design on your part. Use only the very best and cleanest seed. There are always enough weeds in the land without sowing any. If you keep your own seed, put it in new sacks turned inside out. You will then have practically new sacks at the next harvest. In stacking seed or grain of any kind in the barn, always stack the bags on end to minimise the damage by mice. Empty sacks should not be allowed to lie about to be eaten by mice and rot in the wet. If bags are laid out perfectly flat in heaps mice rarely hurt them. As farming is as much a business as any other trade, keep a diary. Record the dates of sowing, services of stallions and bulls, when the rams are put in and taken out. You know then when to expect the progeny. Record your buying and selling, it will enable you to easily make out your income tax return. If you are working on an overdraft at your bank, sell your wheat at harvest time. If you hold 2,000 bush. of wheat for six months and then sell at 3d. per bushel more than the price at harvest you are no better off; besides, you have often to sell at a lower price, then you lose both ways. If your bank balance is on the right side do not keep a very large current account. Idle money is a direct loss to you. Do not attempt too much. A little well done often returns more net profit than a lot badly managed. To attempt too much often causes your seedling to be late, or the land to be neglected for want of time. At harvest the grain is about the paddock unsewn and uncarted, losing weight every day for an indefinite period. The hay is also left in the paddock until after the reaping and becomes very drv. Generally at this time the farmer is overworked and worried, especially if he should have indifferent employes. When things are in this state there are sure to be numerous little wastes and leakages that he cannot attend to, in fact he is so overworked that he often does not notice them at all." In the discussion which followed members generally agreed that married men were usually the most reliable for farm laborers, and every farmer should provide good accommodation for married men. A small kit of blacksmith's tools was very useful. Members thought it more profitable to sell the wheat at harvest time each year than to store it.

ENSILAGE.—It was generally agreed that an old tank, provided it was airtight, provided a suitable pit for the manufacture of ensilage. The Chairman had fed cows on ensilage that had been buried for five years in a tank.

Pine Forest, August 27.

(Average annual rainfall, 13in.)

PRESENT.—Messrs. D. Carman (chair), A. Hewett, G. Inkster, W. Attenborough, S. Barr, R. D. Goodridge (Hon. Sec.), and one visitor.

MIXED FARMING.—Mr. W. Attenborough read a short paper on this subject. He recommended the farmers to provide an ample stack of feed for their animals, as there was always the possibility of a dry season being experienced. With proper attention, dairying would be found payable in the district, especially if barley were grown for green feed and a silo were erected for the conservation of fodder. The Shorthorn was perhaps the best breed. The keeping of pigs would also be found profitable, and he strongly advised all farmers to stack straw. In discussing the paper Mr. Carman said that in the majority of cases mixed farming was advisable in the district. Where cows were kept regular milking was essential.

WESTERN DISTRICT.

Coorale, August 24.

PRESENT.—Messrs. A. W. Hardy (chair), Giles, Riddle. W. H. Wheadon, Atkins, Roberts, Underwood, C. Hobbs, Coppins, Murray, Woodforde, C. Wheadon, Evans, C. Fox, Iles, Weston, Jackson, Kinsley, Cousins, Gregory, H. V. Hobbs (Hon. Sec.), and seven visitors.

TANK-BUILDING AND LIME-BURNING.—Mr. N. M. Roberts read the following paper :—“ Without doubt the supply of water for our households and stock is one of the most important matters with which a farmer has to deal, and the value of a good water supply can hardly be overestimated. Every farmer should build sufficient tanks to enable him to have 12 or 18 months' supply. He would then have an abundance to carry him through a period of drought. If water cannot be obtained by sinking, as is the case in many places, and especially in the mallee country, tanks should be built. Well-sinking is expensive at any time, but is even more so when the quest after good stock water proves futile, as is evidenced in our own district again and again. The question of the size of tanks is one which needs consideration, and one cannot study too carefully the position of his tank. Tanks should neither be too large nor too small. I do not favor constructing tanks smaller than 25ft. by 16ft. by 8ft., nor would I build one with a capacity of over 50,000galls. From what I have seen in this district farmers do not consider the position of the tank or the making of drains of any importance. I am firmly convinced that the most suitable place for a tank is near the bottom of the slope of a hill. I have had several tanks made right in the gully, but on no account would I construct any in a gully again, as I find it far more difficult to get water to run into them in the valley than when they are on the side of the hills. Another point in favor of this position is that when filled the surplus water has a chance of flowing away. Implement sheds, barns, and stables should be built with iron roofs in order to catch all the water possible. Thousands of gallons could be stored if fair-sized tanks were built. If not, the farmer finds himself reduced to water carting—the most expensive and unsatisfactory task he has to undertake on his farm. There are times of the season when he needs more than a normal supply of water, and to meet this demand tanks for storage are absolutely necessary. With regard to the method of lime-burning, I am led to believe that the best result is obtained by making an excavation in the earth 10ft. by 10ft. by 6ft. This hole should be on high ground, so that in the event of wet weather the water can be drained away from the kiln. After having prepared the kiln, it is advisable to cart all the stone and wood required. This being done, proceed with the building of the kiln, by making a bed of leaves, bark, and dry twigs. Upon this place dry sticks, gradually increasing the thickness until you have a layer of heavy, dry wood. The stone, which should be moderately hard, can be broken on the layer of wood into the size of about 4in. Keep the stone to the centre, near the funnel used as a means of creating a draught. Do not put on heavy layers of stone. Cross the next layer of wood, which should be green logs, or preferably, roots, and now put on a heavy layer of stone, keeping it, as before, well to centre of the kiln. Continue placing alternately the wood and then the stone to the desired quantity. Finish with a layer of roots or logs on top, in order to burn the top stone. There need be little fear of melting the stone, as almost upon every occasion some few stones are not burned. I have obtained excellent results from stone brought to the surface by the plough, and would strongly recommend using this in preference to raising stone. If possible choose a calm night for burning, although it does not pay to delay simply because there is too much wind. Be guided by circumstances. If lime is required immediately burn irrespective of weather conditions. One great disadvantage with excavated kilns is the large amount of dirt which always falls in unless the kiln is walled. In building, place the largest logs or roots on the sides. This allows the centre of the kiln to burn out first, thus causing it to fall in, instead of spreading out. Ordinarily the kiln takes three or four days to burn out. The lime being ready, a start can now be made with the concreting of the tank, which has been thrown out, the walls of which should have a 2ft. 6in. batter in 7ft., 3ft. in 8ft. In throwing out a tank one must not lose sight of the fact that there is the same amount of evaporation from a 5ft. deep tank as there is from a tank of a depth of 9ft., so it is advisable to make it as deep as possible. My usual method of making concrete is to mix sand and lime in the proportion of two to one. A bay consists of 30 shovelfuls of sand and 15 of lime. This will take a fair size barrowful of stones broken to a 3in. gauge. The more mixing, the better the concrete will be. If, however, a farmer should have plenty of water, it would be as well to mix the sand and lime in the afternoon and mix the stone in with the mortar next morning. This will give the lime every chance to slacken during the night. I believe this to be the best way. Always put the bottom of the tank in first, with a thickness of

about 7in. of concrete. The continual walking on the floor will cause it to set, and seldom, if ever, have I seen any cracks there. As soon as the floor is finished start building the walls with a thickness of between 5in. and 8in. of concrete. The wise man will get as near the 8in. width as possible. Doubtless it will require far more material, but is it not policy to make a finished job of it than to be everlastingly patching it up? In a large tank I keep going round and round with layers of concrete; by the time the first layer is finished it will be set enough to proceed with the second. Very often the walls fall in owing to the concrete being put on when too green. This should be carefully avoided as it causes a serious waste of time, which possibly may be the means of missing a good rain. I consider it an excellent plan to build the walls of the tank to a height of between 6in. and 12in. above the ordinary level of the ground. This will allow of the walls being banked up with dirt to prevent water getting into the back, which often causes a great deal of trouble. After the concreting has been left to dry thoroughly, the next move is to begin cementing. For this purpose it is necessary to sieve the sand, which should be mixed with the cement in a two to one proportion. Unless one exercises care he is apt to make the cement too wet. This should be avoided, and in no case should too thick a coating of cement be used. The day following the completion of cementing, give the tank a cement wash, which fills up all the wind cracks. After this has been done put on a coat of coal tar before the cement dries, in order that the tar may penetrate farther into the cement and make a better wall." The majority of members agreed with the views and methods of the writer. The Chairman recommended that the concrete walls should not be less than 8in. thick. Mr. Riddle considered such a thickness to be a waste of time and material, provided the backing was sound and good. Mr. Oats (a visitor) also took this view, and stated that, provided the back was firm, 4in. was ample. A loose, uneven backing would require a thicker wall. Mr. Atkins mentioned the importance of not allowing the concrete to dry too quickly. Mr. Giles thought that if the bottom of the tank were rock, the concreting of the bottom should be left until last. The majority of members favored making several smaller tanks in preference to a very large one of, say 200,000galls. capacity, and agreed that stone should not be broken too small, and it was better broken before being put on the timber when building the limekiln. Mr. Riddle said that something in the nature of old sheet iron placed on the top of the kiln to keep the heat in would be beneficial. The best limestone available in this district was that with a pinkish tinge. Considerable doubt was expressed as to the possibility of striking water by well-sinking in the mallee scrub; no one had yet been successful, although it was admitted that very few farmers had made the attempt.

Elbow Hill, August 24.

PRESENT.—Messrs. Cooper (chair), A. Chilman, E. Wake, C. Jacobs, F. Wheeler, S. Wake, E. Story, C. J. Jacobs, H. Wheeler, F. Frieth, G. F. Wake (Hon. Sec.), and five visitors.

DIVERSIFIED FARMING.—This subject was dealt with by Mr. A. O. Chilman, in a paper, as follows:—"In an uncertain district such as this, with a scanty rainfall, it is not advisable to depend on wheat-growing alone. I consider this district an ideal one for stock-raising, providing rabbits are kept in check. There is a sufficient rainfall for growing feed, but the time of the rains is not always the most suitable for wheat. We could make far more use of the summer rains than we do. A dry autumn generally follows a wet summer, therefore we would do well to have about 100 acres or 200 acres of good fallow to sow with barley, oats, or other green fodders for fattening purposes. Take the summer and autumn that have just passed for an instance. We had from 3in. to 4in. during the harvest months, and with the favorable weather conditions that followed the farmers of this district could have fattened enough sheep not only to have supplied Eyre's Peninsula, but Yorke's Peninsula as well. At the same time they could have kept three or four cows in good condition, and secured the benefit of the high price of butter which always rules at that time of the year. We should also devote some time to vegetables, such as turnips, carrots, beetroot, and peas, all of which grow rapidly. These could be sown in a five-acre paddock well worked for the purpose. Any surplus over domestic requirements would come in handy for the pigs, and this kind of food is cheaper than wheat for this purpose. It does not pay to keep more pigs than can be fed properly. Two good sows and a good boar are enough for breeding. If there should be a shortage of feed, sell the young ones as soon as they are fit to wean. The poultry industry is a side line that is sadly neglected on most farms. The fowls are allowed to run wild; the roosters

are never changed, and the consequence is they inbreed, and the farmyard is soon overrun with mongrels and weedy specimens, which are neither use nor ornament. The hens make their own nests, lay a setting of eggs, and sit for three weeks on half-added eggs instead of fresh ones. They may bring out two or three chicks, or perhaps leave the nest before the incubating period has expired. If the poultry is neglected it will not pay. If farmers start with pure-bred fowls, and keep them pure, they will find that there is money in poultry. The Minorca comes first as a laying fowl, and then the White Leghorn. These two crossed produce a good table bird. On no account breed in, as this has a detrimental effect on poultry as well as on stock." Mr. E. Wake thought it quite probable that summer feed could be grown in the district. Mr. H. Wheeler advised the drilling in of oats on stubble land, to which the Chairman objected that horses would not eat them readily. Bare fallow was advisable. Poultry was a profitable adjunct to the farm, the best breed being White Leghorns. Hens should be discarded after their third year. Members generally favored rye and barley as green foodstuffs. The Hon. Secretary was of the opinion that lucerne could be grown for summer feed. There was a difficulty in disposing of fat stock at certain times of the year in this district.

Green Patch, August 26.

(Average annual rainfall, 26in.)

PRESENT.—MESSRS. F. Gare (chair), J. Sinclair, jun., R. Sinclair, W. M. McFarlane, E. Chapman, C. Parker, G. Sinclair, T. Freeman, and C. J. Whillas (Hon. Sec.).

TOP DRESSING CROPS WITH SUPER.—Mr. Parker had tried top dressing oats with super., but the crop had not benefited. Mr. Freeman was of the opinion that in this district the land should be better ploughed and cultivated, and that poor ploughing was the cause of many of the poor crops.

VINES IN BLACK SOIL.—Mr. McFarlane reported that he had found it necessary to root out about four acres of Zante currant vines. The vines had been planted at the bottom of a gully in black peaty soil nine years ago, and until two years ago had made splendid growth, and had supplied a good crop of currants each year. Through the heavy rains the water level had risen to within 2ft. of the surface, and this was killing the currants. Vines on the poorer higher ground were doing splendidly.

Shannon, August 24.

PRESENT.—MESSRS. Proctor (chair), H. Roediger, W. Wemyss, C. Wemyss, H. Proctor, A. Habner, W. Watkins, V. Gordon, and J. J. Cronin (Hon. Sec.).

FALLOWING.—Mr. A. Habner contributed a paper on this subject in which he stated that the land should be ploughed as early as possible in order to allow the winter rains to soak in. He would plough to a depth of 3in. This would disturb the stumps but not the clay. The fallow should be worked about the middle of September. This would give an opportunity of working it again before summer, and land so worked would not set down. To get fallow in proper order it should be worked three or four times, which sweetened it and stored up nitrogen. A good deal of attention should be paid to the milk thistle, because, if allowed to spread it was very hard to eradicate. If turned in deeply it would not come up again before the next spring; but if left on the surface it would grow with the summer rains. Sheep were invaluable for checking weeds, as it was an easy matter to destroy them after they had been fed off. Shoats were a considerable source of annoyance in this district. He had tried to get rid of them by ploughing, but they were as thick as ever. A stubble burn was the best means of riddance, and to facilitate this the land should be worked frequently, instead of being ploughed 6in. deep to get the stumps out. In the discussion which followed, Mr. C. Wemyss preferred to always plough deep and work the ground well, if weeds were on the land or not. It was necessary to obtain a good seedbed for the following year. Mr. H. Proctor believed in cultivating with a disc cultivator and then harrowing well.

Utera Plains, September 21.

(Average annual rainfall, 14in.)

PRESENT.—MESSRS. H. Venning (chair), J. and M. Abrook, W. Stephens, T. C. Hornhardt, G. Barber, F. H. Haywood, W. Lee, Hill, C. Binley, R. Hill (Hon. Sec.), and three visitors.

WATER CONSERVATION.—Mr. J. Abrook read a paper on this subject in the course of which he stated that the supplies of water in the district were limited in number and uncertain. In view of this it was advisable to provide artificial catchments such as iron roofs or cement floors. An inch over an acre amounted to 20,000galls., and a 14in. annual rainfall would supply 280,000galls. In discussing the question, members agreed that something should be done to influence the Government in the direction of providing artificial water runs as well as tanks.

SEEDING.—In reply to a query as to the best time to sow fallow land in a district where the rains were usually late in May, members generally recommended that this class of country should be sown with an early variety of wheat, somewhat later than it was customary to sow stubble.

Yabmana, July 27.

PRESENT.—Messrs. J. N. McCallam (chair), H. R. and A. McCallam, J. F., J. Y., and A. Robertson, G. W. Story, J. Penna, F. Schirmier, and M. K. Frost (Hon. Sec.).

CARE OF FARM REQUISITES.—In a paper on this subject the Chairman impressed on members the necessity of providing proper accommodation and protection for harness, implements, &c., used on the farm. The harness should be kept in a closed room, protected from winds, and should be oiled or greased at least twice a year. Neatsfoot oil and tallow fat could be used for the latter purposes, and this rendered the leather more pliable and it was less likely to crack. Continuing, the paper said:—"Everyone should be methodical. The cornsacks from which the seed has been taken should be well shaken out and hung over a wire under a roof, and just before harvest-time all holes should be mended. Sheepskins would often bring double the price if properly stretched and dried. All drying should be done under cover." In discussing the question members generally considered that neatsfoot oil had a tendency to rot the harness. Mr. G. W. Story said that suitable timber was scarce in the district. Jarrah posts and galvanized iron were the cheapest building materials. Mr. A. Robertson considered that a wall of brush or stumps was a harbor for rabbits. In reply, the Chairman said that a straw shed was more economical for new settlers. When farmers became established they could erect more expensive sheds and buildings.

Yadnarie, September 20.

PRESENT.—Messrs. W. L. Brown (chair), G. H. F. W., and J. Dreckow, J. A. Kruger, A. Spriggs, R. H. Parbes, R. B. Deer, L. H. Marston, C. J. Mowat, S. H. Pearce, J. J. Deer (Hon. Sec.), and one visitor.

HARVESTING HAY.—In a paper on this subject, Mr. Pearce stated that land on which hay was to be grown should be carefully cleared of stumps and sticks, in order that the progress of the binder might not be hampered. It was advisable to overhaul the binder some time before it was to be used. Wheat hay was best cut when the straw was white up to the first notch. It should not be left until too dry, as the grain became hard, and very frequently had an ill effect on the horses. When oats were cut green they had a tendency to be somewhat bitter; the best time for cutting was when the straw was turning pink. A mixture of wheat and oats was best for hay. A farmer was well advised to have on hand a somewhat larger supply than he anticipated using in case of unforeseen happenings. Cut lines should be put through the wheat crops in order to prevent running through the ripe crop with the harvester. Strips should also be cut around the fences and sheds, and the stubble ploughed in, to act as fire breaks. Hay should be cut between two and four days before stooking, and remain in the stooks for from six days to 10 days. If stacked too soon injurious effects were likely to follow the feeding of the hay to stock. Before a stack was commenced, a good layer of logs should be put down, great care being taken to see that no holes which would allow of the ingress of rabbits were left. Stacks with round corners were to be preferred. If care were taken to keep the centre of the stack well filled, there would be no difficulty experienced through the rain soaking inwards. The roof should be constructed with the heads of the sheaves outwards. If a stack were required to stand for over 12 months, it was advisable to thatch it. Wherever practicable, the hay should be carted before reaping was commenced. If, however, the wheat ripened before the hay harvesting was done with, stripping should be got on with immediately. The stripper was best when used on rough or new country, as the chaff was saved, less difficulty was experienced with the mallee leaves in the machine, and the draught was lighter. The harvester should be overhauled some time before it was to be used, and

spare parts should always be kept on hand. The comb, especially, should be in good order. A 5ft. comb was quite wide enough for this district. When cool weather prevailed the speed of the horses should be increased but during hot days, they should be driven slowly. Neglect of the wind board was likely to result in considerable loss. A mixture of resin and oil, boiled, was very useful to apply to belts. When the bags were taken off the machine they should be stood in rows, to facilitate the work of sewing and counting. The wheat should be removed from the paddocks as soon as possible. In discussing the paper, members generally agreed that it was undesirable to sow wheat and oats together for hay. It was better to mix the two crops when chaffing. Castor oil was an excellent dressing for the harvester belts. It should be vigorously applied on the inside and outside of the belt after the day's work was done.

Yallunda, August 24.

PRESENT.—Messrs. F. Olsten (chair), T. Forrest, G. Provis, S. L. Dix, S. C. Fairbrother, A. Cabot, G. Gill, J. Winch, H. P. Cabot, W. Bryant, A. Price (Hon. Sec.), and one visitor.

POULTRY ON THE FARM.—The Chairman contributed a paper on this subject in which he stated that poultry was one of the best paying by-products on the farm. Considering the attention they got they paid equally as well as sheep. If farmers kept an account of the profit from fowls for 12 months the results would often be surprising. It was not so much noticed because eggs were generally taken to the store in small quantities and placed against the account. For wool from 85 ewes and wethers and 15 lambs he obtained £20 18s. The sale of eggs from 80 hens, besides the value of eggs used in the household, was £19 11s. In addition, he reared 100 chickens, which at five months old he valued at 1s. 6d. each. He sold several cockerels at 2s. 6d. each, which made a total of £27 1s. Leghorns were good laying fowls, but it was difficult to keep them inside the yards. He preferred the Silver Wyandottes and Orpingtons, as they were excellent table birds. To improve the laying qualities of the strain, eggs from the best layers only should be set. He did not favor cross breeding. In this district there was a shortage of lime, which was necessary to prevent the hens laying softshell eggs. Fowls running at large were freer from lice and were stronger than those kept shut up. They did a great amount of good if turned into a fruit garden, as they were excellent scavengers and cleared out insects. In the discussion which followed Mr. A. Cabot said that sheep were more remunerative, as they enriched the soil to a great extent. Members generally agreed that, although it paid every farmer to keep poultry, sheep were more profitable in that they helped very largely in keeping the land free from weeds.

EASTERN DISTRICT.

(EAST OF MOUNT LOFTY RANGES.)

Berri, August 31.

PRESENT.—Messrs. S. Phillips (chair), H. Wescombe, A. P. Wishart, R. Stahling, B. A. Arndt, F. R. Arndt, R. Roska, A. Symons, F. Symons, A. Jarvis, J. McGilton, W. H. Wade, and H. R. Antuar (Hon. Sec.).

PREPARING LAND FOR IRRIGATION.—Mr. H. Wescombe read the following paper:—“Having obtained possession of the land the average man wishes to secure some returns as soon as possible, and begins at once to prepare it for planting. So eager is the inexperienced man that he often overlooks many important points in preparing and laying out his holding. In view of the large area that will probably be thrown open for irrigation during the next year or two, too much cannot be said on this subject. There are two classes of land, from an irrigation point of view, i.e., the high land and low land. The former generally consists of more or less sandy soil, while the low lands are heavy and in many cases stiff clay. Therefore it is necessary to deal with these separately, and as we are more interested at present in the high land, I propose to deal with this first. Remove all stumps and large roots to a depth of at least 12in. Where suitable timber is found in cutting up the trees it should be used for posts and the balance carted

to some out-of-the-way place and stacked for firewood. Brush and other rubbish can be piled into heaps and burnt. The ashes should be scattered about before ploughing, otherwise a tree or vine planted at that spot will most likely fail to grow. My experience in using ashes is that they should be used in moderation, say, not more than 2yds. or 3yds. to the acre. In ploughing the land endeavor to break it up thoroughly to a depth of 6in. to 8in. If it is hard and dry it will not be possible to plough to a depth of more than a few inches. In this case plough again after the first rain or irrigation, if possible, and also run the harrow over it. After the first ploughing it may be necessary to do a certain amount of grading to enable the settler to irrigate his land properly. Avoid grading if possible, as it is expensive work; and it is not a good plan to remove all the surface soil from one particular place. In grading, consideration should be given to surface drainage as well as to the watering of the block. Should there be no natural outlet for the surplus water it is a good plan to scoop out a good size dam at the lowest part of the block, and after the flooding, if there should be any water lying on the block, this can be drained into the dam, where it will probably come in useful for watering stock. Should there be a small grazing paddock in the block, let it adjoin the dam, so that the dam will serve two purposes. The next consideration is the provision of irrigation ditches. In dealing with these, too much care cannot be taken to have them in their proper places. Some of the points to be taken into account are—(1) In what direction do the rows to be watered, run? (2) Will the rows be too long? (3) Will the rows have sufficient fall? (4) Are the rows too steep to water without washing the land? These points should be carefully considered before deciding where the channels are to be placed. If the rows are too long, say, over 7 chains in length, the top gets too much water before the bottom trees are supplied. The result usually is that in a few years time seepage appears in the lower parts of the block. If the water is run on the side of the hill without sufficient fall to enable it to run freely the land takes in too much water and this is likely to cause seepage. If the land is to be watered down a steep grade it will be necessary to water with a very small stream for each row, otherwise deep gutters will be washed out. In using a small stream of water the rows must be short, say 5 chains, or the water will take too long in reaching the bottom trees. If these points are noted, and the land is judiciously watered in after years, seepage will not appear to the extent that it has appeared in some of the older irrigation settlements."

(To be continued.)

In reply to questions, Mr. Wescombe said there was little fear of seepage if the rows did not exceed 7 chains in length, but 5 chains was better. Seepage in the older irrigation settlements was mainly due to the fact that the main channels were left for 10 or 12 years before being concreted; whereas, if this difficulty were encountered at Berri, it would be due to overwatering at the top of the rows. It was advisable to water across a hill, provided sufficient fall could be obtained.

QUESTION BOX.—A number of questions were dealt with. It was thought advisable to plant vine-cuttings where they were to remain if rooted vines were not procurable. But this should not be done on heavy land. Planting should be early if the water supply was assured. The best time for planting the main crop of potatoes was August and September, the most suitable varieties being Redskins and Up-to-date. Heavy cropping varieties of vines could advantageously be planted for distilling purposes.

Coonalpyn, September 26'

(Average annual rainfall, 17½in.)

PRESENT.—Messrs. Wall (chair), Bone, Cronin, Venning, J. Hill (Hon. Sec.), and one visitor.

POULTRY.—Mr. E. E. Williams contributed the following paper on this subject:—"The best breed of fowl for the farm is the Wyandotte. Birds of this breed should be of medium size, with square cobby bodies, short legs, and small bone. They are splendid layers, especially in cold weather, laying fair-sized eggs, more or less tinted. Chickens are hardy and reach maturity early. The pullets lay early. They are unrivalled for general purposes, and for crossing with Old English and Indian game. The flesh and skin are creamy-white and of the finest flavor and quality. The question of the production of a fair-sized marketable egg is a consideration, and the eggs of the Wyandotte, especially in the first year, are on the small side, though they will usually reach the 2-oz. standard in the second year. Some dealers object to the small eggs, while others accept them without demur. Eggs should be graded, but, if the farmer has to suffer, the consumer should not pay as much for small as for large eggs. The cost of rearing chicks

is an important item, and the earlier the young cockerels are killed the better for the farmer. It is surprising the quantity and quality of flesh obtained from young cockerels. The cost of housing is important. Five-foot wire netting is a sufficiently high fence for this breed, although it is probably the most active and busy of the heavy breeds. In the *Journal of Agriculture* for July, in the article on Poultry Tick, Mr. Laurie says, *inter alia*, 'In the colder and wetter districts the tick does not thrive.' This coincides with the view of one of the best known poultry breeders in the State, who used a good deal of woodwork on his poultry houses. In the absence of tick it becomes possible to construct cheaper and warmer houses. A 3ft. wall as the back of the house would be of advantage. Scrub timber should be used in front, and built high enough to give sufficient slope for a broom-bush roof to be used. This provides a warm house in winter and cool accommodation in summer. The divisions could be made of stone or wire netting. Wire netting should be placed over the house at the front, in order to prevent the fowls flying out. The yard should be from 30ft. to 50ft. long by 10ft. wide, and with not more than 10 fowls in each. It will pay better to keep the fowls yarded, and provide exercise and variety of food for them. A good mash can be made as follows:—Chaff or greenfeed, including potato peelings and other waste well boiled, mixed with an equal weight of bran and pollard in the proportion of one of bran to two of pollard. Feed it in a warm state, not hot. Two or three times a week poultry meal in proportions mentioned in the instructions should be given. At mid-day give as much green feed as they will eat. The greater the variety the better. Grain should be given at night. The water should be changed frequently. Permanganate of potash in the water once or twice a week will be of benefit. Cocky chaff or manure should be given for scratching. Under these conditions fowls will lay all through the year, and will pay better than if running wild. Some time ago I kept fowls in a suburban yard, discovered the tick, and got rid of the poultry. Many months after I had occasion to shift the back fence, during which operation many of the palings became loose and had to be nailed on afresh. After nailing one or two, I noticed that blood was literally running down the palings, and on investigating I found the space between the palings and rails to be thickly populated by tick. After removing the fence I again kept poultry, but by placing all houses away from the fences and using as little wood as possible, I was not again troubled with the pest."

Parilla Well, August 1.

PRESENT.—MESSRS. J. E. Johnston (chair), G. Pahl, B. Pahl, W. and F. Foreman, D. and J. Ferguson, J. W. Johnston, J. S. Johnston, E. H. Leak, L. G. Neville (Hon. Sec.) and three visitors.

FALLOW.—In a short paper on this subject, Mr. J. E. Johnston expressed the view that in all districts where the rainfall was not high, fallowing was necessary for successful wheat-growing. The work should be carried out early, in order that the winter rains might be retained in the land. Usually it should be finished by the end of August. Sandhills and flats should be ploughed separately. The former were best ploughed down hill with the skim plough, the depth of work being about 3in. or 4in. Following working, the stumps should be picked and the land harrowed crossways. Sandy land should then be left until seeding, as over-cultivation usually resulted in drift. The flats could be worked with the skim plough with the mouldboards taken off. Harrowing should follow a rainfall. Sheep were very useful for keeping down the rubbish. In discussing the subject, Mr. J. W. Johnston said sandhills should not be ploughed to a depth greater than 3in. Land carrying a heavy growth of shoots was best dealt with by the disc plough. Mr. J. S. Johnston said sheep were necessary for keeping down the weeds, and they also helped to keep a dust mulch, which assisted in the conservation of moisture. Mr. L. G. Neville emphasized the importance of working fallow after rains in the spring, or during the summer and autumn.

Parrakie, September 21.

PRESENT.—MESSRS. A. J. Beelitz (chair), H. Deiner, C. Heinze, T. W. Randall, F. W. Gravestocks, J. G. Temby, C. E. Hammond, R. L. Beddome, R. G. Jose, F. S. Dayman, N. Good, M. Kildea, T. Lewis, T. Willis, J. A. Ferme, S. R. Good, J. O'Hara, A. C. Hamoister (Hon. Sec.), and three visitors.

POULTRY.—In a paper on this subject, Mr. R. E. Jose stated that all farmers should keep up to 200 laying hens and a few roosters, the majority of which should be killed

when chickens. The difference in sex could be noticed when the chickens were a fortnight old, and even earlier in the lighter breeds, such as White Leghorns and Minorcas. It was unprofitable to keep hens after two years of age. White Leghorns, Silver Wyandottes, and Black Orpingtons were the best breeds for laying. He preferred the White Leghorns, as they were non-sitters, laid large eggs, and were very easy to rear. They stood the cold weather better than the others, as their feathers were thicker. The houses should face the east and should be made of galvanized iron, which did not harbor vermin. Perches should be placed about 18in. or 2ft. from the ground for either light or heavy breeds. Fowls should be fed at least twice a day. The morning meal should consist of boiled wheat, or bran and pollard mixed. Epsom salts should be given in the food once or twice a week. This prevented them getting too fat. The evening meal should be given an hour before sunset, and should consist of sound wheat, with chaff or straw. This gave the fowls exercise before going to roost. Lucerne or maize should be grown and fed to them at least once a day in the summer, preferably at mid-day. Charcoal should be given to provide grit, which was scarce in this district. The drinking water should be kept in the shade, and changed frequently. He preferred hatching with an incubator, as the chicks were healthier than those hatched by a hen. Attention to the housing, feeding, and breeding would prove fowls one of the best paying lines on the farm. In discussing the paper, Mr. C. E. Hammond said he preferred White Leghorns crossed with the Orpingtons. Mr. F. W. Randall would rear roosters until they reached the age of six or eight months, and then sell them. Mr. F. W. Gravestocks did not favor pure-bred fowls. He preferred White Leghorns crossed with Buff Orpingtons, and he would keep hens until three or four years old. Mr. Jose, in reply, said the egg-laying competitions provided a proof of the superiority of the pure-bred fowls. Infertile eggs were better for export and had a better flavor.

Pinnaroo, September 21.

PRESENT.—Messrs. B. L. Harfield (chair), M. Beckwith, A. W. Burman, F. G. Bonnin, J. Docking, F. H. and R. Edwards, H. Fewings, L. M. Ferguson, H. C. Hill, W. H. and W. A. Kelly, C. Lee, F. Laycock, M. McCabe, E. H. Parsons, J. Scales, L. Small, W. Venning, P. H. Jones (Hon. Sec.).

QUESTION BOX.—The programme for the evening took the nature of a question box, and many items of interest were discussed. In reply to a query as to whether it was possible to improve the quality of cow's milk by altering the feed, Mr. F. H. Edwards considered that if good feed were supplied to the cows both the quality and the quantity of the yield would be improved. Mr. Parsons said the addition of bran to the ration resulted in a high percentage of butter fat, and Mr. Venning had obtained best results by using copra cake. The merits of the various breeds of cattle were discussed. Mr. Edwards thought it was of more importance to ascertain whether the cow came from a good milking strain than the breed of the animal. He also expressed the view that the feed of the cow had a great deal to do with the profit. Mr. Venning thought that the milking Shorthorn was the most suitable for this district, as it was readily saleable to the butchers for slaughter. Mr. Scales also preferred a large-framed cow, providing, of course, that the quality and quantity of milk were satisfactory. The Chairman considered the Jersey the most suitable. Mr. F. H. Edwards did not think sufficient manure was used by farmers in this district. As the nature of the land varied to such a degree he would advise each farmer to make experiments. He could not agree with all that had been said by the Director of Agriculture. When phosphates were first introduced he experimented widely. At Enfield, where they usually cut for hay, he always used 1cwt., but, for an experiment, had applied 2cwts. per acre. The extra super. had induced increased growth, and although the crop did not blight it was "fluffy," and so he thought it did not pay to apply heavy dressings. The Chairman mentioned that a farmer from the Adelaide Plains district, who raised fat lambs for market, favored heavy manuring as a means of increasing the grass yield. Mr. R. Edwards believed that a heavy dressing of super. improved the grass, but until it was possible to cater more for grazing lands, he did not think the scheme advisable. He was of the opinion that ½cwt. was ample for new land in this district. Mr. Venning thought they could not look upon Pinnaroo lands in the light of grazing, but he favored heavier dressings of manure than were customary. Mr. Bonnin had recently conversed with a northern farmer on the subject of obtaining a selection of seed from another district, and that gentleman had mentioned that he had been farming for 30 years and had not found it necessary to make any alteration in his seed. Other farmers in the same district had continued on a similar course for a lengthy

period. Mr. Venning preferred to select his seed from fallow or new land. He did not consider it necessary to make a change, as by so doing there was always a risk of getting an inferior sample and there was no guarantee of freedom from other wheats.

Renmark, August 26.

(Average annual rainfall, 11 in.)

PRESENT.—Messrs. H. DeWitt (chair), J. S. Huggins, M. B. Geneste, E. Cole, H. S. Taylor, L. Basey, R. Nuthall, H. D. Howie, C. J. Everard (Hon. Sec.), and one visitor.

SPRAYING SOLUTIONS.—Mr. Geneste reported that some of his Sultana canes were badly affected with oidium last year. He sprayed them with soluble sulphur in the early spring, and this year the canes were quite clean. Mr. Howie had delayed spraying until late last year, and some of the canes were badly marked. Mr. Nuthall had been successful in obtaining good results by spraying early and dry sulphuring later. Bordeaux paste was generally condemned by members, but all agreed that Bordeaux mixture was very good. Mr. Cole found that stock solutions of bluestone and lime would keep as long as desired, provided they were kept separately. When the lime solution was being made, the slaked lime, after being mixed with the water and treacle, should be strained. Mr. DeWitt expressed the view that the treacle caused the water to take up 17 times more lime than when the treacle was not added. Mr. Cole had secured good results from treating peach aphids with a spray of red oil. The first application was made early in August, and the second one a week later. Last year he had successfully dealt with the aphids with tobacco wash, but only after six sprayings. Mr. Basey suggested the use of paper painted with axle grease and carbolic, as a protective band for fruit trees against caterpillars.

DECAY IN ORANGES.—Mr. H. S. Taylor referred to the fact that English and Californian experience confirmed the opinion that decay in oranges arose from cuts or bruises on the skin. Messrs. Basey and Cole considered it necessary to wear gloves when handling this fruit.

Wilkawatt, August 31.

PRESENT.—Messrs. J. Ivett (chair), W. J., D. F., and D. Bowman, C. and T. Sorrell, J. W. and F. W. Altus, G. W. and H. Brooker, A. J. McAvaney, F. and B. Spackman, W. R. and M. Neville, M. Hayes, F. W. Gasmeir, B. Tylor, P. Rigney, P. Maher, W. J. Tylor (Hon. Sec.), and seven visitors.

POULTRY.—Mr. F. Spackman, in a paper on this subject, stated that in order to get together a good yard of poultry a great deal of care and attention were necessary. Good, warm, iron houses should be provided, as timber and straw tended to harbor tick and lice. Draughts should be carefully guarded against. For laying, White Leghorns were best, with Black Orpingtons next. Breeding pens should be provided for each separate breed, and eggs from the best only should be set. Inbreeding was not advisable. The birds should be regularly fed with small quantities, one hard and one soft meal daily being recommended, with green food such as cabbage, lettuce, or lucerne, always available. Cracked limestone or charcoal should also be provided generously. Nests should be on the earth, as the eggs were then able to draw up therefrom the amount of moisture which they required. Where the hens were sitting on straw, or in a box, the nests should be occasionally sprinkled with warm water. Sitting hens should be well fed. Generally the pure-bred hens would not be found the best mothers. Chicks and their mothers should be shut up for a few days after hatching, and fed on soft food for the first week or so. Bran and pollard mixed with skim milk was recommended, and sweet skim milk was most suitable for drinking. It was a good practice to add a little sulphur to the drinking water in summer, and salts in winter. In the discussion which followed Mr. Neville preferred the Black Orpington breed. He favored breeding in the spring time. Mr. Spackman said that some of his fowls had eaten a good deal of bonedust, and they had thrived on it. Members generally favored breeding all the year round.

STUMP-PICKING.—Mr. B. Tylor read a paper on this subject, in which he advised the setting aside of small areas on sandhills on which to stack stumps. These should be gathered up before seed time. It was essential to clean land intended for hay-growing, in order to prevent damage to machinery. The fire rake would usually effectively deal with small stumps after harvest, and very little trouble should be experienced with the machinery through these. On no account should the stumps be placed alongside a fence, or close to a road, because of the harbor they afforded vermin. Very frequently, also,

when the stubble was being burnt the stumps caught alight, and posts were destroyed. Where rabbits got into the stacks, they could easily be destroyed by erecting a netting fence around the heap.

SOUTH AND HILLS DISTRICT.

Cherry Gardens, August 27.

(Average annual rainfall, 35.3in.)

PRESENT.—Messrs. S. W. Chapman (chair), T. Jacobs, C. Lewis, A. Broadbent, C. Ricks, A. R. Stone, J. Tozer, H. Jacobs, H. Lewis, A. Jacobs, J. Lewis, T. Jacobs, jun., E. Broadbent, S. H. Curnow (Hon. Sec.), and two visitors.

ALMONDS.—Mr. Burpee (a visitor) stated that some of his almond trees, although they flowered well, did not set a crop of fruit, and the foliage dropped prematurely. He had tried Bordeaux mixture, but the result had not been satisfactory. Mr. Ricks did not think almonds would do well except on limestone ground, but Mr. Curnow instanced cases of large crops being returned from trees on almost pure sand, which was borne out by Mr. Jacobs. Mr. Chapman found little good resulted from spraying almonds with Bordeaux mixture.

A RETROSPECT.—The feature of the meeting was a paper by Mr. C. Ricks, in which he traced the work done by the Cherry Gardens Branch since its formation 20 years ago. Reference was made to the influence the institution had exercised in the direction of improving agricultural and horticultural methods in the district, and mention was also made to various matters of public policy in which the Branch had played an important part.

Clarendon, September 3.

(Average annual rainfall, 33½in.)

PRESENT.—Messrs. A. L. Morphet (chair), J. Piggott, W. A. Morphet, A. and A. A. Harper, L. Masters, J. Wright, F. Sheidow, T. B. Brooks, J. Spencer, C. Mathews, A. Phelps (Hon. Sec.), and four visitors.

WATER CONSERVATION.—Mr. T. B. Brooks read the following paper on this subject:—
“In a dry climate such as ours, where little rain falls during the summer and autumn, stock may be seen suffering from scarcity of water, and farmers therefore lose valuable time carting water. Where a large number of iron-roof sheds have been erected close together, large underground tanks can be utilised to hold sufficient water for stock; but where large quantities can be conserved, dams are the cheaper means of storage. With a 5ft. buckscraper and with fair going, 100 cubic yards of earth per day should be got out. If the land is not too wet and boggy, and with a little scooping each season, an abundant supply for stock should be obtained and a fair amount might be used for irrigation. Large quantities may be stored by building banks across the gullies in places where the clay is good. The water could then be run through pipes to flats lower down where fodders could be grown for summer and autumn feed. This would improve property values by at least 100 per cent., and stock would not require so much hay or dry feed which, during seasons such as this, could be marketed at high prices. Every cubic yard of earth taken out of a dam provides space for 168galls. of water; and if 100 cubic yards per day are taken out there is a storage capacity of about 17,000galls. With banking across a gully the amount of storage will depend on the grade of land; but in all probability, where 100 cubic yards of earth is removed and placed on the bank, it will provide storage for 10 times that amount. Our average rainfall is 33½in., and if each farmer stored that quantity off 25 acres he would never be short of water, and his stock would not suffer during the long summer months.” In the discussion which followed, members generally agreed with the ideas advocated by the writer.

Gumeracha, July 30.

(Average annual rainfall, 33in.)

PRESENT.—Messrs. J. Porter (chair), J. B. Randell, J. Monfries, A. Moore, H. Norsworthy, H. V. Lee, A. H. Cornish, and W. B. Randell (Hon. Sec.).

FODDER CONSERVATION.—Mr. J. Monfries read the following paper on this subject :—
“The present season should impress on every farmer the necessity of providing food for cows during winter, when it is always scarce in this district on account of the cold and severe frosts. There is nothing better than silage for cows and young stock. It is not at all likely that the conservation of forage in the form of ensilage will ever supersede haymaking, but its value for feeding purposes must steadily increase in favor where dairying is conducted to any extent. No artificial or conserved fodders can equal good grass. The most palatable and nutritious substitute, especially for cows in milk, is well-made ensilage. The character of the silage, to a large extent, depends on the class of crop used and the method adopted to fill the silo. In America and Canada initial difficulties have been overcome, and there are over half a million silos in use, and no dairy farm is complete without one. In Australia very few farmers have persevered sufficiently to master the details of ensilage-making, but a season such as we have just had should force our attention on to this important subject. The most convenient method of constructing a silo in this district is to cut into the side of a hill. This should be lined with single brick and coated with cement, the front wall being of double brick with a strong frame similar to a door frame built in about 4ft. from the bottom of the silo. The frame is made so that red gum planks 2in. thick can be placed in as the silo is being filled. The silo is oval in shape with smooth sides, so that the crop can be readily trampled down. The roof is constructed so that it can be taken off and put on as required. A silo such as this can be easily filled from the top, and when ready for use the ensilage can be taken out with ease by backing the dray in below and dropping the feed into it from above. There is no waste, as a layer can be removed each time from the surface of the pit. The crop must not be put in at too dry a stage, as there will not be sufficient moisture to produce fermentation, and the ensilage will therefore be dry and tasteless. Should it be dry, it should be watered while filling, but the ensilage will be of inferior quality. When filling the pit the crop should be thoroughly trodden in around the edges so that the upper portion, about 5ft. or 6ft. from the top, will receive sufficient pressure to ensure a proper fermentation and preservation, otherwise it will become mouldy and practically useless. When the pit has been filled it is advisable to cover the ensilage with damp chaff to the depth of a foot, and it should be weighted with heavy timber or kerosine tins filled with sand. Any vegetation that stock will eat in its natural state will make good ensilage. It is said cattle assimilate ensilage better than any other food, and the reason is that the change effected in the silo is nearly equal to that brought about in the first stomach of ruminant animals. It has been proved that by thoroughly cultivating and manuring the land, ample food for one cow can be grown on an acre by adopting the silo system. A mixture of oats, peas, wheat, and vetches makes excellent ensilage; and lucerne, if cut when just in bloom, cannot be excelled. Maize also makes first-class ensilage, especially if it is chaffed. An advantage in making ensilage instead of meadow hay is that ensilage can be made in wet weather. It is necessary to feed hay with it, however. Since using ensilage I have not lost a cow through dry bible; it keeps them in perfect health. With the aid of the silo an abundance of succulent food can be carried right through the year. In the dry months, from December until the end of April, when greenfeed is very scarce, the silo, full of fresh green fodder, can be opened and the cows will milk as in the spring. Ensilage will enable more stock to be kept on the farm. We cannot continue to keep our farms in a high state of fertility without stock, and we cannot keep stock profitably unless we provide feed for them during the dry months of the year. The silo will greatly assist in this direction.” In the discussion which followed Mr. A. H. Cornish said he had attempted to make ensilage, but on account of defective methods it had proved a failure. He was convinced, however, that it was a great help to dairymen. Lucerne, and also Scotch thistles if cut while young, made excellent ensilage. Mr. J. B. Randell had tried it some years ago, and was convinced that there was no question about the value of ensilage if properly made. Care had to be taken in regard to the temperature, as too high a temperature would cause it to burn and be quite useless. The heat could be regulated by the speed of filling the pit or building the stack. If sweet ensilage were needed a high temperature should be maintained. It was also necessary to guard against the material being too dry, especially so with the large hollow strawed fodders. He considered the best crop was meadow grass and also chaffed maize, the latter giving a yield of from 30 tons to 40 tons per acre if well grown. Cows were very fond of it. New South Wales experts did not look with

favor on lucerne as a crop for ensilage, but favored feeding lucerne hay and ensilage, which proved a perfect ration. With ensilage he believed in feeding hay, bran, and chaff. He also thought the pit system far superior to the stack, as there was far less waste. Mr. A. Moore had tried a small stack of maize which had turned out a failure, but he was convinced that the manufacture of ensilage was the best means of conserving fodder for cows. Mr. Norsworthy was of the opinion that it was very beneficial for dairy cows, especially during bad seasons when the natural herbage was short and scarce. Mr. Porter had tried ensilage-making on a small scale, putting down wheat and dandelion, from which a great deal of moisture drained, but the solid contents were in first-class condition. The size of Mr. Monfries' pit was 14ft. x 14ft. x 15ft.

Gumeracha, August 27.

(Average annual rainfall, 33in.)

PRESENT.—Messrs. J. Porter (chair), J. B. Randell, B. Cornish, A. H. Cornish, H. V. Lee, J. Monfries, and W. B. Randell (Hon. Sec.).

MANURES.—In discussing the benefits arising from the use of various manures, Mr. J. Monfries was fully convinced that land in the hills required lime. He had noticed that in one of his paddocks, where there was a small outcrop of limestone, the crops were heavier than elsewhere. Mr. A. H. Cornish had used as much as 2cwts. of bonedust per acre for peas, with no apparent increase in the crop, and the following hay crop showed no benefit. After a dressing of ashes the improvement was wonderful, being evident for fully five years. Some years ago he had tried Thomas phosphate with no appreciable results. Mr. B. Cornish said that many years ago a light dressing of salt had been applied to his land with good results. He believed in bonedust. At first he used 2cwts. to the acre, but found better results followed when 1½cwts. were used. Land in this district needed more rest, and should be ploughed every two years. Weeds could be kept down by scarifying. If the soil were well stirred up and exposed to the sun it would give better results. Mr. Lee had come to the conclusion that the hills land was too wet, as a rule. He had tried commercial manures during wet seasons without good results, and during dry seasons, with no manure, he had obtained good crops. Mr. W. B. Randell remarked that during his two years' experience of farming in Gumeracha he had found the best results followed a crop of peas with a dressing of 1cwt. bone super. to the acre.

Hartley, August 24.

(Average annual rainfall, 16in.)

PRESENT.—Messrs. B. Wundersitz (chair), J. F. Tydeman, W. Bermingham, J. M. Hudd, W. Brook, S. Pratt, F. Brunes, G. Hill, W. Richardson, J. Stanton (Hon. Sec.), and four visitors.

HOW TO MAKE MEETINGS MORE ATTRACTIVE.—In a paper on this subject the Hon. Secretary pointed out the value of the Bureau as a means through which farmers could approach the Government, which looked for opinions from the various Branches on matters of moment in the districts in which the Branches existed. Necessary advice on agriculture could be obtained from experts through the medium of the Bureau. Although a great deal was gained by the interchange of opinions at the meetings, there was sometimes a lack of business-like methods. When a subject was before the meeting for discussion, the Chairman should call upon the members to speak, instead of allowing them to speak at will. This would have the effect of inducing members to take keener interest in the subject. New members were sometimes backward in discussing a subject, and this frequently resulted in their losing interest in the meeting. In the discussion which followed members generally agreed that if the ideas expressed were carried out, more interest would be created in and good done by the various Branches.

FIVE YEARS AS HON. SECRETARY.—Reference was made to the fact that Mr. W. Bermingham had held the position of Hon. Secretary to the Branch for the past five years, during which time he had rendered much valuable assistance to the Bureau.

Ironbank, July 26.

PRESENT.—Messrs. G. Pole (chair), C. Morgan, E. Coats, C. Coats, S. D. Evans, R. Coats, C. J. Hill, W. Slater, F. S. Coats, F. Brown, L. G. Ahrens, and W. Coats (Hon. Sec.).

ARBORICULTURE FOR THE HILLS.—The following paper was read by Mr. C. J. Hill:—
“Afforestation claims our serious and immediate attention. The work of vandalism goes on despite the pleadings of a patriotic press. Certainly the hills are not being denuded of trees in the same manner that open and undulating country is, but scarcely a thought seems to be given to the reservation, much less the planting out, of suitable timber trees any more here than there. Nowhere is the scarcity of timber more perceptible than on the farmsteads of the hills; in every direction one is confronted with the serious fact that all exposed woodwork is wearing out—decaying, tumble-down yards, sheds, field and garden fences are met with in every locality. Culverts, bridges, and all outside woodwork have to be renewed within a generation or two from the time of construction. The good price obtained for firewood forms a severe temptation to turn valuable timber trees into ready money, in the absence of a ready means of converting them into sawn timber. It is regrettable that the art of pit-sawing is an almost forgotten one in many places, but it presents no insuperable difficulties to persons accustomed to the use of tools. Nearly every farm or garden has a few trees or dry logs lying about in the way. The farmer, with the help of his sons, or the boys themselves, during the winter months, by the outlay of about £2 can purchase a sawyer's plant by which very rough-looking stuff can be converted into the most useful material, because for durability, the trees of the tiers yield a timber that cannot be beaten anywhere. Our much despised stringybark, for instance, will stand in the ground better than most imported timbers, but above ground, nothing that we import can approach it. I recommend the good old-fashioned pit-sawing because of the inexpensiveness of the plant. Certainly no one, unless in possession of a forest of trees, could afford to erect machinery. This is not considered a timbered country, therefore the farmer is unable to run off with a few logs to the mill and return home an hour later with a load of timber. I notice that beautiful young gums (which term comprises stringybarks) are being mercilessly slaughtered for firewood. The district councils are censurable for not conserving, for their own future use, good sound young trees; it would be an easy matter to send a practical man to mark trees for reservation against the vandalism of the scrub-cutter. Seeing all these things, is it not our bounden duty to provide and conserve timber patches for our own and the next generation? I say our own advisedly, for a pine, of the right kind, and many indigenous hardwoods can be cut into timber from 20 to 40 years from planting, to say nothing of the immense benefit in ornamentation of properties, and for cattle shelters. Now is the planting season, and it is my purpose in this paper to name those varieties that I think most suitable for waste lands of the range country generally, and for our own locality particularly. There is a brief interval just now, before the hum of gardening begins, and I desire to impress on you the vast importance of this matter to ourselves and our successors. Do not lay out large plantations, that are sure to be neglected, but make it your annual duty to put in, say a week, at planting, protecting, trimming, and training those set out in previous years. One would suppose that those kinds that are indigenous to each locality would be the best doers, being born to those conditions, but experience does not bear out this supposition in every case. For instance, the Tasmanian blue gum grows much more rapidly in the ranges of this State than our own blue gum; likewise the sugar gum, although a habitat of the elevated country of the middle north, more readily adapts itself to the steep, rugged spurs of the Mount Lofty Ranges than the red gum does; and all of them grow much more rapidly in South Africa, California, and all other countries where the growing season is also the rainy season. Although our blue gum is a very superior timber, excelling in hardness, strength, durability, and weight, it is a slow grower, having many natural enemies, the worst of which is the parasitic mistletoe. Let the blue gum grow where it is at home—on stony spurs, with marly clay underlying, and having a northern aspect, but for planting out artificially, let it be the Tasmanian variety. Red gum cannot be approached for durability, but it is at home in undulating country and in flats at a considerable altitude, but for steep, shady hillsides the sugar gum is better, but I have yet to learn whether or not the timber resists the white ant as the red gum does. The calophylla of Western Australia, though not equal to our *rostrata*, is a stronger timber, and better suited for beam work, and would, perhaps, do in the ranges here, being a hardy tree, tall and rapid of growth, and requiring moisture, such as our hills afford. I wonder our Forest Department does not supply this tree, also the *toort* gum, which ought to do well in dry situations having shallow subsoils, in fact, growing strongly where other eucalypts fail. If there is any part of South Australia suitable for the jarrah it should be on gravelly spurs south of Mount Lofty, as the dry northern winds are considered inimical to its growth, and the moisture-laden air from the south is congenial. The same conditions apply to the karri gum of Western Australia. Of Victorian timber trees the almond-leaved stringybark (*messmate*) should certainly find a home in the tiers. It is, probably, the most useful timber tree of Victoria,

and although the obliqua and capitellata are of almost equal utility, and are properly valued in that State, yet here, where they both do well, especially in steep, shady, and uncultivable situations, they get a bad time, being considered fit only for firewood. Where these eucalypts grow naturally they should never be sacrificed for imported varieties, but should be thinned out and protected from bush fires—their greatest enemies—and in 25 years' time they would yield fine shapely 'sticks' for the sawyer, equal to anything in the world for rough beam and outside work. These timbers have not had a fair deal—any kind of treatment is considered good enough for a 'stringy.' In cutting these logs, the boards should never be ripped out on the back, that is, at right angles to the quarter grain, but should be ripped out in a direction, as near as possible, with the quarter cracks. Boards cut like this never buckle. Flitches should be stacked, and ripped into smaller stuff when needed, and they will come out, and retain, quite a different appearance, that is, clean and fresh, instead of stained and dirty looking—the condition in which they are invariably found, particularly in the form of fruit boxes. Another Victorian tree—the mountain ash—should find a congenial habitation here. It yields a stronger timber than the stringybarks, is free from gum bladders, and is largely used in South Australia for wagon work. Of an almost infinite variety of woods of New South Wales, some three or four kinds of ironbark take first place for outside work. It is the only timber that approaches South Australian blue gum, but I am of opinion that the tree would not succeed in Mount Lofty country, but it should in range country of the north, unless there is insufficient humidity in the atmosphere. Of the half dozen kinds of pines supplied by the Forest Department, there seem to be only three suitable for timber, viz., Remarkable, Canary Island, and Longifolia; these are handsome trees, and vigorous growers, delighting in the cold. Experience teaches that the Remarkable is, every time, the best to set out for timber purposes. For box ends pine is indispensable. The Remarkable pine will grow and flourish everywhere in the ranges, and even on the roughest land. On strong land it grows branchy, therefore, instead of planting close to induce height and slenderness, it is better to give room and trim off the lower branches as the top moves upward, but do not check the tree by severe lopping. The callitris, or native pine, grows slowly, but on poor sandy ranges and hillocks of the drier parts, it flourishes. It yields a wonderfully durable timber for general carpentry and outside bush work, completely baffling the white ant; its cultivation, therefore, should be encouraged by the Government for telegraph poles. I would like to see the native pines of Eastern Australia taken on by our very worthy and active Conservator of Forests, and tried in the north of this State; they should be always planted or sown on ridges or mounds, for that is where they are always found. The *Cal. robusta* grows tall and straight as a candle. The oaks of my acquaintance, though affording the toughest of timber, have poor fissile properties, and are most difficult to work. They are not particularly at home away from sandy river banks. Therefore, I recommend the native pines as being of paramount importance to arboriculturists."

Ironbank, August 23.

PRESENT.—Messrs. C. Moigan (chair), J. Morgan, S. D. Evans, L. Ahrens, G. Pole, F. Brown, W. Coats (Hon. Sec.), and two visitors.

BEANS.—In a paper on this subject Mr. F. A. Coats said the best time for planting Canadian or French beans was from September 30th onwards, when the soil had become warm. Bonedust should be sprinkled on rows 26in. apart after the ground had been dug, and then hoed in with a fork hoe. The drills should be drawn out with a hoe to a depth of about 6in. Into this the beans should be dropped at intervals of between 3in. and 4in., after which they should be covered with fine soil. The plants would be up in three or four weeks to a height of about 6in. They should then be fork hoed to a depth of 4in. or 5in., care being taken not to disturb them. Banking served the dual purpose of providing a channel for water between the rows and a guard against the wind breaking the heavily-laden stalks. Early in the season watering should be confined to alternate rows, but when the weather became hot or dry the plants should be watered weekly. The crop should be picked twice a week, and water should be supplied on the day following every other picking. Beans should be carefully protected from wind and snails. In discussing the subject Mr. Evans contended that super. was better than bonedust for this vegetable. Mr. Brown believed in planting two rows 1ft. apart and then leaving a space of 3ft. Mr. J. Morgan would only plant the beans 1in. deep, and some of the members would put them 6in. apart in the rows.

Kanmantoo, August 29.

(Average annual rainfall, 17in.)

PRESENT.—Messrs. A. W. Hay (chair), J. Shepherd, W. Shepherd, W. Downing, H. G. Pym, E. Shepherd, R. Talbot, L. Wooley, R. Downing, S. Downing, A. Mills, T. Critchley, W. Mills (Hon. Sec.), and four visitors.

STABLES.—In a short paper on this subject Mr. H. G. Pym stated that the first consideration in connection with the erection of a stable was the position. For the particular district in which he resided the usual practice was to have the back of the stable facing the east, and wherever possible the building was put on the side of a hill with the back down hill, in order that refuse soaked away. Each horse should have a separate stall, and pegs should be provided for the harness. The stalls should be not less than 6ft. wide, and wherever possible the building should be constructed of stone with an iron roof. The continuous recovering necessary where straw was used for roofing outweighed the advantage of more even temperature which it gave. In addition, the iron roof provided a good catchment for water, and there was not the danger of fire that existed in the case of the straw roof. The occasional application of an antiseptic was recommended and regular cleaning out of the stables advised. In discussing the paper Mr. W. Downing expressed the view that 5ft. was quite wide enough for the stalls.

Longwood, August 24.

(Average annual rainfall, 37in.)

PRESENT.—Messrs. W. H. Hughes (chair), G. W. Doley, J. Roebuck, E. A. Glyde, J. C. Blakley, A. F. Furniss, H. Vogel, J. R. Coles (Hon. Sec.), and two visitors.

HOMESTEAD MEETING.—The homestead of Mr. G. W. Doley was visited. The orchard was inspected and various matters of interest discussed. Mr. Filling had successfully dealt with club root by dipping the roots of trees before planting into a mixture of equal parts of lime, soot, and wood ashes, in water. Mr. Blakley tabled Egyptian clover 12in. in height, it being the second cut. The seed was sown on April 8th, and the first cut had been 16in. high.

MacGillivray, August 27.

PRESENT.—Messrs. R. Wheaton (chair), H. Ayris, J. Matthews, A. J. Nicholls, H. E. Petras, A. Stirling, sen. and jun., and H. E. Williams (Hon. Sec.).

BLACKSMITHING.—Members and their families attended at the homestead of Mr. Stirling, where the host gave a practical demonstration and lecture on blacksmithing. He first showed the difference between good and inferior coal, pointing out that the latter made more clinkers than the better coal. Fine gauge coal was desirable. When pointing iron it should first be tapered on the square; haphazard hammering caused the material to split. Tempering chisels, both for iron and wood work, was demonstrated. After heating the steel, rubbing it on the ground cleaned the surface and enabled the smith to better see the tinge of color as it spread towards the point. In the case of a cold chisel the plunge into cold water was made immediately the bluish hue reached the cutting edge. In the event of the edge being jagged, the temper should be taken a trifle sooner, and the tool then ground back to the tempered zone. When a wood chisel or plane-iron was removed from the fire it could be dipped into cold water immediately and withdrawn, then placed on red hot iron until the straw shade appeared. Cooling off when this reached the cutting edge gave the required temper. In preparing for a weld both pieces of iron should be dumped before fashioning the scarfs. These should be sloped back a distance equal to the thickness of the bar. A cross-cut put on the scarfs prevented the pieces from slipping when struck by the hammer. The hammer first dealt with the two fine ends, locking them into the butt of the opposite scarf; and then the middle was easily done, provided no side blow was struck before a firm union was effected. Any bulge remaining might either be worked down or wasted off in the fire. There was a difference in wasting and burning iron, hence the operator must open the fire in order to watch that the former stage was not exceeded. Another style of preparing for a weld could be adopted when heavy work was on hand, and this consisted in pointing one bar and making a dish in the other to correspond. The joint might be effected either by fusing them in the fire or they could be forced together otherwise. The correct heat for each weld was shown. Eyebolts were left small in the eye until welding was completed, after which, by forcing a round bar through the opening, it was easily enlarged.

Square heads for bolts were simple to make if any old nuts were available. Another way of putting a head on a bolt was to put it in the vice whilst it was hot, holding it just tight enough to avoid pinching, and tapping the head down. For making a square beneath the head the bolt needed to be held in a piece of iron having a square hole of the required size. The sharpening and treating of augers was explained. Some users ground the round of their augers from the cutting spiral upwards, leaving the diameter of this slightly greater than the ground part. By doing so it was found that less trouble occurred on account of the tool jamming. Putting cast iron on wearing surfaces, such as the points of ploughshares, was shown. After making the share hotter than the thin cast iron, the two were placed in contact and kept so until sufficient of the iron adhered to the share. When cooled the part so treated gave a surface of great hardness. Corns in horses' hoofs were almost invariably found on the inside. When shoeing such hoofs the wall should not be cut away unless the bearing happened to be too forward. By leaving this a foundation was provided for the shoe, which thus acted as a protector to the corn. The corn should be cut away. A horse with its front feet deformed was exhibited. The trouble was due to the animal being unable to stand up during a protracted illness. One way to prevent such a development was to stand the invalid in water for a period of several weeks before malformation had a chance. Another method was to bleed the feet from an incision made at the apex of the frog. When horses were being shod it was advisable to clean the frog to see if any foreign objects such as pebbles or stakes were present. Some members shod their horses and others never found it necessary to do so. Reports were made of horses rubbing against fences and other fixtures. One member had found what appeared to be a species of flea on his animals. He had resorted to combing with a very fine comb, followed up by applications of kerosine. This treatment eased the trouble, though no permanent riddance had yet been effected. The horse which had been most badly infested lost condition until the apparent cause had been combated, since when it had improved. The garden, where provision had been made against wind by the erection of brush fences, was inspected.

Meadows, July 29.

(Average annual rainfall, 34in.)

PRESENT.—Messrs. C. Ellis (chair), T. B. Brooks, J. Catt, W. J. Stone, S. Smith, W. Nicolle, Jas. Stone, F. Nottage, H. A. Kleemann, A. L. Ellis, W. H. Bertram (Hon. Sec.).

FODDER CROPS.—The following paper was read by Mr. H. A. Kleemann:—"The difficulty of providing fodder for stock during the cold winter months may be overcome if systematic efforts are made to grow summer fodders for green feed and for ensilage. Farmers everywhere are beginning to realise that slipshod methods of feeding stock will not do, and that the only way to improve the quantity and quality of animal products is by raising forage crops. The object, of course, is to supplement the natural pasture by raising succulent food at a time when that class of feed is scarce. It is to the small farmer that the growing of forage crops should appeal strongly. Men on small holdings must turn their attention to this phase of agriculture, as it is only by adopting methods of intense culture that they can hope to be successful. Both for dairy farming and the raising of fat lambs, forage crops are of the utmost importance. It is necessary, first of all, to consider what crops are most likely to suit the climatic conditions of the district. Let me first of all take lucerne. It is a splendid winter feed in the form of hay, chaff, or ensilage. It should be sown when the severe frosts are over. One of the best kinds to grow is Hickory King. It has been proved that five acres will keep 20 cows in full profit all the year round, providing either ensilage or hay is available for the winter months. At Wood's Point, at Messrs. H. W. Morphet & Co.'s farm, several hundreds of dairy cows are kept, and they are mostly fed on lucerne. There is a steadily growing demand for lucerne hay in South Australia, and this year at the Murray Bridge Experimental Farm only one-quarter of the orders could be met. The yield varies from seven to 12 tons per acre yearly. An annual yield of 10 tons per acre at £4 per ton would bring in £40. If a farmer grows more than he requires, he can readily convert the surplus into cash. Some say that lucerne taints the milk, but if it is allowed to wilt a little before feeding, this is not so. It is also good for pigs and poultry. Maize is a strong, vigorous plant that grows rapidly through the summer months. It can be fed as a green fodder without any fear of ill effects, and it also makes the best ensilage. At Messrs. Kirkham's dairy farm, at Ashbourne, it is extensively grown and converted into ensilage in an overground silo. Maize is susceptible to frost also, and should be sown in October. It should produce at least from 10 to 15 tons per acre at Meadows. Dairy farmers would be well advised

to grow a certain acreage of maize every year, as a safeguard against a dry season. To harvest a crop of maize, throw it into a silo, as the bulk of the crop is ready at one time. It is quite certain that farmers will have to conserve forage in the form of ensilage to a far greater extent than they do at present. It has been proved that both lucerne and maize can be grown here, and as every farmer here keeps dairy cows, the growing of these crops will enable them to stock more. The work of feeding and milking have to be done at present, and it will only entail a little more time in looking after the extra cows. Sorghums are likely to have a much larger range of cultivation than maize, though where maize can be grown, it is preferable as a fodder crop for several reasons. Maize is a richer and stronger plant, and it makes a better class of green fodder and silage, and there is not the same danger in feeding it green as there is in the case of sorghum. Sorghums have the advantage over maize that they give a good second growth, whereas with maize, unless it is irrigated, there is very little second growth. Sorghum grows well in light soils, and will stand a severe drought. The cultivation necessary is similar to that for maize. At certain stages of its growth it is dangerous to give to stock. It loses its poisonous properties in a few hours after it is cut and stacked, or placed in a silo, and is also safe to feed after the seed begins to form. It gives two or three cuttings a year, and also provides feed just at the time when the paddocks are bare. Mangolds constitute the best winter fodder for dairy cows. They are an expensive crop to grow, on account of the thinning and handling involved. They stand the cold well when the full leaf stage is reached. When ready to harvest, they should be pulled—never cut—and they should not be tailed. If properly stored away, this fodder would stand through the winter months, and feed well in the summer. They do not taint dairy produce as turnips do. Rape is the best fodder for fattening stock. It can be sown in the autumn or spring, but it must be sown on land that is in good heart. It does well on land that has carried a crop of beans or peas. Kale has several advantages over rape. It stands right through the season and the following winter, and comes again very early in the spring, when feed is scarce. With kale there should be 2ft. or 3ft. between the rows, and the land should be well worked. It should be sown in spring, and fed off more lightly than rape. Not much special attention is required, but, of course, in common with anything else, it does better with good cultivation. Of the millets, the Japanese is the best. The cultivation required is similar to that for sorghum. If cut early in the season it gives a second growth, and seed should be sown at the rate of 2lbs. or 3lbs. per acre. Rye is a good early green fodder, but it is not much good for hay. Oats and barley mixed, sown early, also gives good results. Mustard grows very fast. It is a good food for cold weather, but the stock should be put on early, before it becomes too strong. Some of the crops I have mentioned are grown here, but only on a small scale. More must be done if this district is to take its place as a dairying centre. The necessary rainfall is forthcoming, and it behoves the farmer, if he wishes to keep abreast of the times, to experiment more. Every farmer should try at least one experiment a year, in order to ascertain what his land will produce. He will not only benefit himself, but will provide object lessons for others in the district." Members generally agreed that the cultivation of fodder crops was neglected to a large extent in the district. The Chairman was of the opinion that maize was better for ensilage than for green feed. Members were agreed that lucerne was a first-class summer fodder, but it would not grow in the winter months on account of the cold. Lucerne flea also was troublesome in the early spring.

Meadows, August 26.

(Average annual rainfall, 34½in.)

PRESENT.—Messrs. G. Ellis (chair), J. Catt, W. Nicolle, J. Morriss, T. B. Brooks, S. Smith H. A. Kleemann, A. L. Ellis, J. Stone, F. Nottage, and W. H. Bertram (Hon. Sec.).

CONSERVATION OF WATER.—Mr. F. Nottage read the following paper on this subject:—"The non-appearance of the usual rains last autumn has caused farmers to consider what provision should be made for conserving water for such a late winter as the one just experienced. Being accustomed to an average rainfall of 35in. in this district the farmers have become somewhat careless, and the result has been, where insufficient rainwater tanks and dams for stock have been available, water carting had to be resorted to, which involves a considerable loss of time and labor. When one considers that an inch of rain on an acre of ground amounts to over 22,000galls., some idea may be gained of the immense quantity of water that goes to waste when the ground becomes thoroughly saturated. By the construction of dams, a part of this can be conserved for use during the hot weather and when no rain falls. A suitable place in a gully where it only requires

a substantial bank to be made should be chosen for a dam. With the aid of the plough and scoop this should not be a very long or costly undertaking. The common red clay of this district is excellent for holding water. A dam an acre in extent would be sufficient to irrigate several acres of ground for the growing of fodder crops for stock, and would supply the wants of the natural feed, which has suffered severely this year. In the past the farmers of this district have depended too much on the natural herbage, consequently, when a long spell of dry weather comes, cattle, in particular, become very low in condition, and the milk supply suffers accordingly. There is no doubt that irrigation will have to be resorted to if the farmer wishes to make the best use of his land. There is always the possibility of a late season." In the discussion which followed members agreed that not enough attention had been given this question on account of the high average rainfall. Mr. J. Morriss thought it a mistake to construct a dam in a place where the water lay in winter, as it would silt up too quickly. He intended to sow half an acre with lucerne in October, and irrigate it with the aid of an engine, pumping plant, and sprinklers.

Morphett Vale, August 27.

(Average annual rainfall, 22½ in.)

PRESENT.—Messrs. A. C. Pocock (chair), F. Rosenburg, A. Anderson, T. Higgins, J. Perry, H. O'Sullivan, L. F. Christie, A. Connole, W. Goldsmith, E. Perry, H. V. Sprigg, T. Anderson, E. E. Hunt (Hon. Sec.).

FEEDING PIGS.—The Hon. Secretary reported excellent results from feeding a sow and litter on equal quantities of bran and pollard, mixed with milk to a thick slop, and left standing for a few hours.

MANGOLD WURZEL.—Mr. Pocock read a paper on this subject, in which he stated that mangolds were an excellent crop for the southern districts, and their value was not fully realised by farmers. The best varieties for field cultivation were the Oblong and the Globular, with sub-varieties of Red, Orange, and Yellow. Six pounds of seed per acre should be sown in August or September. They were better suited to stiff soils and a comparatively dry climate. The seed should be steeped in water before sowing, and plants could be transplanted in order to fill up any gaps. The seed should be sown to a depth of about ½ in. to 1 in. and about 12 in. apart. A dressing of from 3 cwt. to 5 cwt. per acre of salt was most suitable, but green stable manure should never be used, as it caused the roots to grow forked, thereby reducing their value and increasing the cost of gathering and cleaning. Root crops should only be planted on land made rich by manuring. The land should be ploughed early and deep, worked to a fine tilth, and kept free from weeds. Mangolds should be pulled before they went to seed, and should be stacked and covered with straw.

Port Elliot, September 21.

(Average annual rainfall, 20½ in.)

PRESENT.—Messrs. H. B. Welsh (chair), J. Chibnall, J. Brown, H. Welsh, H. Green, and W. E. Hargreaves (Hon. Sec.).

CANNING AND DRYING FRUIT.—Mr. W. E. Hargreaves read the following paper on this subject:—"Sugar is not necessary in canning fruit, but is used as a syrup flavoring. A syrup made of 4 lbs. or 5 lbs. of sugar to 1 gall. of water is sufficient generally. The fruit should be just ripe and sound, not bruised, and quite freshly gathered. Decay is caused by organisms which cannot live longer than a few minutes if the fruit is subjected to a boiling temperature for a time. The fruit must be sealed up hot, in order that living germs cannot gain admittance. The air is loaded with germs of moulds, mildews, ferments, etc., therefore canned fruit must be used within a reasonable time after being opened, or it will spoil. When glass jars are used, and they are the best, a folded cloth on the bottom of the boiler, and one also between the jars, will prevent breakage. Before filling, place the jars in a boiler of cold water, and bring them to a boil on a slow fire. Take the boiler off the fire, and let it stand until cold. This will temper the jars. Then fill them with the fruit and syrup, and stand them up to the neck in the water, with the cloth under and around, and bring the water to boiling point on a slow fire. Then fill them to the top with hot syrup. As soon as the fruit is done, close the jars tightly. Dip their heads in melted beeswax before they are cold. A kerosine tin with one side cut out makes a good boiler for canning small lots. If larger quantities are to be done, have three or four boilers. Some fruits require more boiling than others, but do not boil the

fruit too long, or some will crack and spoil the appearance of the bottle. Apricots halved, with the stones removed, only need about six minutes; apples quartered or halved, according to the size, about 12 minutes; grapes, 10 to 12 minutes; strawberries, 10 to 14 minutes; pears, halved or quartered, 18 to 20 minutes; plums, 10 to 12 minutes; peaches, halved and stoned, eight to 12 minutes; cherries, six to seven minutes. On no account should they be boiled on a quick fire, or the jars will crack and the contents spoil. A little practice will soon teach one more than a lot of reading. Drying fruit is one of the easiest ways we have of preserving. The greatest mistake to be guarded against is overdrying. The drying is completed when no water will squeeze out of the fruit. Apples should be peeled and cored, and either left in rings or slices. If one wishes to keep the apples white when dry, drop them into a weak brine of about 1lb. of salt to 8galls. or 10galls. of water, as soon as they have been peeled. This keeps them white until they can be sulphured. Then the white color is permanent. Place the apples on the trays made to fit the sulphur box, and then a few live coals of fire in a tin under the trays in the box. Put the sulphur on the coals, and shut the box up for 15 to 20 minutes. After this either put the fruit in the evaporating machine, or dry in the sun if the weather is warm. Apricots should be ripe, but not soft. Cut them in two and take out the stones, and lay them on the trays cut side up, and sulphur the same as for apples. Leave them in the sulphur box for 60 minutes or so. Sulphuring is not necessary; it gives the dried product a bright color, at the expense of the flavor. The Dutchess pear, known as the William bon Chretien, is a first-class fruit when dry, and is the best pear we have for the purpose. It should receive the same treatment as the apple, only the pear is not peeled. Cut the fruit into two or four, according to the size and the weather, and sulphur the same as apples. The drying of prunes and plums is simple. Never dry a plum with a sour thick skin, such as the Diamond and Egg plum. They do not dry well, and are very sour, even when dried. The Pond's Seedling, Green Gage, Orleans, and several of the sweet plums, are among the best. The Silver prune, Italian prune, Prune D'Agén, and the French prune are the best. All these, but the Silver, are dark. Where drying is carried out on a large scale, the dark plums and prunes need not be sulphured. Light or yellow fruits for sale should be put through the sulphur box. The prunes should be ripe. To pick them in the right stage will necessitate going over the trees two or three times. The prunes are not all ready to pick the same day, and green, under-ripe fruit is worthless when dry, and will spoil the sample. To hasten the drying process, dip them in a boiling lye for a few seconds. Then dip into a cask of clean cold water to wash the lye off. The lye causes a lot of small cracks in the plum, and it therefore dries much more quickly. If the weather is warm this dipping process is not needed. Prunes for sale should carry a nice gloss, and to get this, when dry they should be put into wire baskets, and dipped into a tub or cask of hot clean water, with olive oil or glycerine floating in it. Then spread them out to dry. This will also kill all insects. The peach is dried with the same process as the apricot, only some kinds require to be peeled, or their woolly skin spoils the taste and appearance of the fruit when dried. If a few of our largest growers went into the drying business we should not hear so much about glutted markets when our stone fruit is in season. Dried prunes, apples, and apricots will sell well when the glut is over. Dried apricots make better jam than can be made with the fruit when taken direct from the tree. We should be able to compete with Denmark in drying fruit. We have long, dry summers, and our cheap land will grow good fruit. It only needs plenty of cultivation, and we have no water rate and other heavy expenses. There should be a big future for this part in fruit drying, as we have railways and a shipping harbor close to our door."

Strathalbyn, August 27.

(Average annual rainfall, 19½ in.)

PRESENT.—Messrs. Cockburn (chair), T. Collett, F. S. Traeger, H. T. Moore, W. Hall, E. Hall, F. Dunford, W. Watt, J. R. Rankine (Hon. Sec.).

BREAKING LIGHT HORSES.—In a paper on this subject Mr. Collett, who had had experience in the Northern Territory with wild horses, stated that this class of horse was hard to quieten, and some were not of much use when broken in. When breaking in young horses, plenty of nerve and ability were needed. He preferred mounting in the open rather than in a yard. When breaking in to harness, a strap should be passed over the rump, and the ends of the shafts should be tied around each front leg in order to prevent too much play in the tugs of the backband.

COST OF WHEAT-GROWING.—In discussing the table set out by the Monarto South Branch, an estimate was worked out for the cost in this district. A 50-acre paddock,

valued at £7 10s. per acre, rental value 5 per cent., land to be fallowed, and an average yield of 21bush. to the acre, was taken as a basis. Rent for two years, 16s. per acre; ploughing, 5s.; cultivating, 5s.; harrowing, 2s.; drilling, 2s.; rolling, 1s.; super. 4s. 6d.; seed, 3s. 6d.; harvesting, 7s.; cornsacks, 3s. 6d.; carting, 1s. 9d.; depreciation of stock, 5s.; total, £2 15s. 3d. The return of wheat, 21bush. at 3s. 6d., £3 13s. 6d.; profit per acre, 18s. 3d. The cost of producing 1bush. of wheat was 2s. 7½d. The above prices were considered the general rates in the district, i.e., those which a farmer would charge if hired for the work. An extra profit came to the farmer, as he charged the cost of production as if paying by contract. An indirect income was the grazing before and after the crop was taken off.

Uraidla and Summertown, September 2.

(Average annual rainfall, 42½in.)

PRESENT.—Messrs. E. Hart (chair), E. Hawke, R. N. Cobbledick, H. G. Dyer, H. F. Johnson, J. Rowe, G. Prentice (Hon. Sec.).

GARDENING.—In a paper on this subject Mr. J. Rowe said that there was a tendency among gardeners to endeavor to put in too large an area without doing the work thoroughly. Good digging and careful ploughing were always necessary for root crops, and it was advisable to plough at least twice and use the harrows often in order to secure a good tilth. Wherever drains were made it should be seen that they were of sufficient depth to serve their purpose. Heavy applications of stable manure, bonedust, and chemical manures were necessary, and every attempt should be made to keep the weeds out of crops. In discussing the question, Mr. R. N. Cobbledick said that it was a bad policy to rush in crops. In a number of cases gardeners would find it more profitable to put in a smaller area of vegetables and grow more greenfeed for their stock. In reply to the remarks of members, Mr. Rowe mentioned that good results had been obtained where the practice of harrowing potatoes just when they were coming through the ground was adopted.

Woodside, August 26.

(Average annual rainfall, 31in.)

PRESENT.—Messrs. R. P. Keddie (chair), H. F. Rollbusch, C. W. Fowler, W. King, W. J. Morcom, J. Lauterbach, C. J. Sampson, A. S. Hughes, and J. Morcom (Hon. Sec.).

PASTURES.—Mr. Rollbusch read a paper in which he discussed the question of the improvement of the grass pastures. It was decided that the paper be again read at the Conference of Hills Branches to be held at Meadows on October 21st.

Woodside, September 25.

(Average annual rainfall, 31in.)

PRESENT.—Messrs. R. P. Keddie (chair), F. W. Baldock, W. King, H. Rollbusch, G. Johnston, G. J. Sampson, J. Drummond, J. Lauterbach, C. W. Fowler, A. S. Hughes, J. Morcom (Hon. Sec.), and one visitor.

POULTRY.—This subject was dealt with in the following paper by Mr. G. J. Sampson :—“Poultry-keeping is a profitable industry and a very great help to the income of the farm. There can be no question that the Leghorn is the most consistent layer in warm climates; but as it is almost useless for a table bird, it is not the best bird for the farmer. It has been laid down by some writers that the Light Brahmas and the Plymouth Rocks are the most profitable birds, being good layers and quick growers. If a pure strain is to be kept, probably the Plymouth Rock will be the most serviceable. I have found the Silver Wyandottes crossed with the Indian Game the best. They are hardy birds and splendid layers. The young roosters grow quickly, and with proper care and attention will be fit for the market at eight months old. I find that it does not do to have more than 50 fowls in one flock and sleeping in one house; in fact, 30 is quite sufficient. The houses should be warm and rainproof, with plenty of ventilation. The roosts should all be on a level and not more than 2ft. from the ground. In feeding, we have largely to be guided by the food supplies obtainable. In this district we have plenty of greenfeed for them in certain parts of the year; and in a dry season there are supplies of kale, rape, cabbage leaves, mangolds, all of which are suitable. Ground charcoal and lime should be scattered about. The grain should be wheat of the best quality. Watering must never be neglected,

and all water vessels must be kept clean and should be filled with fresh clean cold water from the spring twice daily. A flock of 40 fowls will give a yearly return as follows: Each bird will lay, on an average, 150 eggs which is equal to 500 doz., at 11d. per dozen, £22 18s. 4d. yearly; deduct the cost of feeding, £6 5s. 4d., and you have a profit of £16 13s. yearly. From this it will be necessary to write off depreciation on cost of houses and probably some loss in stock. Add to this the value of the birds you raise for the market. One hundred chickens can easily be hatched every year, and there should be no difficulty in securing 3s. each for them; 100 birds at 3s. equals £15. The cost of rearing, viz., £5 2s. being deducted, leaves a profit of £9 18s., the total return from the fowls being £26 3s. 4d."

SOUTH-EAST DISTRICT.

Mount Gambler, August 10.

(Average annual rainfall, 31½ in.)

PRESENT.—Messrs. Wedd (chair), Major, Botterill, Sutton, Sassanowsky, Keegan, Smith, Wheeler, Holloway, Bodey, Kennedy, Pritchard, Watson, Ruwoldt, Kilsby, Pick, Schlegel, Krummel, Cooper, D. A. Collins (Hon. Sec.), and Mr. Colebatch (Superintendent of Agriculture in South-East).

TELEGONY.—Mr. Colebatch said the subject of "telegony" was generally defined as the alleged influence of a previous sire on the offspring of the same female by another sire. The belief was still a very popular one amongst farmers and stockbreeders. It was not known when the idea arose, but it was referred to far back in history. Probably when man began to breed stock he became cognisant of variations in type. In some cases he might believe it was due to the influence of the first sire, and in other cases he might think it resulted from maternal impressions. He briefly referred to the earliest references to the theory in history, and said it was not till the year 1820 that they had the first record, with details, of what appeared to be the telegonic infection, or saturation, of a female by a male. That was a remarkable case, and there had been none recorded like it since. Lord Morton, when in India, had presented to him a young chestnut mare of seven-eighths Arab blood. When he returned to Scotland he brought the mare with him, and at the same time introduced to the country a quagga sire. The quagga was an animal related to the horse, and was remarkable for its stripes and other markings. It belonged to South Africa, and was now quite extinct. He crossed this quagga with the Arab mare. The first product of this crossing was a hybrid, bearing the markings more or less of the sire and of the dam. Then he sold the mare, and she was mated for three years with a black Arab stallion. The first foal—a filly—showed distinct stripes on various parts of the body, and was also said in the main to resemble the quagga type. In the following year a colt foal was bred, and showed markings similar to the quagga; and the third foal showed the same thing. Lord Morton stated the facts in a letter to the Royal Society, and it was not surprising that a case like this took a firm grip, and that the belief in telegony became more widespread than ever. Coming from Lord Morton, and supported by such apparently reliable evidence, it was accepted without question by the society. Even such naturalists and evolutionists as Darwin, Dr. Carpenter, Agassiz, and Herbert Spencer accepted it as true, and almost solely on the strength of Lord Morton's case; and it was not until recent times that the theory was subjected to experimental tests in a scientific manner. Professor Ewart, Professor of Natural History in the University of Edinburgh, at his stock-breeding farm, began to experiment on the lines of Lord Morton's case, and similar experiments were carried out in other parts of the world also; and so far the experimenters had not been able to get in any one instance a clear confirmation of the doctrine of telegony in any class of stock. The question then arose, "How do you get over Lord Morton's hybrids?" On investigating the matter it was found that paintings had been made by an eminent artist of Lord Morton's hybrids, which paintings were now hanging in the museum of the Royal College of Physicians, London, and when these were examined closely they did not bear out exactly the descriptions given of the animals by Lord Morton. The stripes, for example, were not nearly so marked in the foals of the

Arab horse, and in some other respects the foals resembled the Arab. It was further ascertained that the mare had been bought in India, and there was a probability that the other strain of blood in her was Indian. It was well known that among some of the Indian pony breeds there was frequent evidence of stripes appearing on certain parts of the body. In fact, in the case of some Highland ponies there were more stripes in pure-blooded animals than were shown to exist on those foals of Lord Morton's in the pictures. And even among the cases where the crossing was between extreme types (and it was held that it was more marked when the crossing was between extreme types) there had never been any cases of telegony such as that described by Lord Morton. He thought, therefore, it was too far to go back to bolster up the theory on that case when there were more likely and equally satisfactory explanations at hand without any stretch of the imagination whatever. Public beliefs were based merely on hearsay evidence. In the journals many cases that looked at first like telegony were found. For instance, it was said that the influence and characteristics of the blood horse Blair Athol were found to descend for many generations in succession; but that was what was termed prepotency. In cattle there were cases where Polled Angus cows were crossed with a Shorthorn bull and afterwards mated with bulls of their own breed, there seemed to be evidence of the Shorthorn influence in the progeny of those cows. The same thing was sometimes noticed in the case of sheep, where, for example, Highland sheep were crossed with the Leicester. The same also occurred in the case of dogs. These were worth nothing, however, as proving the theory, because it was necessary, in the first instance, to be absolutely sure of the pedigrees of the animals, otherwise a whole host of probabilities were admitted. Then, too, the beliefs were not uniform. Some believed that telegony was the influence of the very first sire a female had. Therefore it was for that that some breeders of the Bedlington terrier mated their females first with a bulldog, in order that they might afterwards get the square jaw and fighting characteristics of this description of terrier. Again, the time that this supposed influence lasted was not long. In two or three generations the female might be ready to produce pure progeny. There were some people who believed that every fresh sire left his own amount of impressiveness on the mare, so that by the time she had had half a dozen foals she would have the influence of half a dozen sires mixed up in her. Other people, again, believed that the influence could even be caught by the sire. That was said particularly among cattle breeders: that if, for example, one crossed a Shorthorn bull with Galloways or Polled Angus cattle the following sire would imbibe certain qualities of that cross, and impart them when mated again with Shorthorn cows. Others said telegony would not show itself with the first cross, but with the second; that if you crossed a mare and a donkey, and afterwards used the mare with a stallion of her own breed, it would not show in the first foal, say a filly, but that if that filly were mated with a sire of her own breed certain features of the donkey would appear in its foal. Professor Ewart, at first a strong believer in telegony, expected to obtain evidence experimentally that would establish the truth of the doctrine. In looking at his results, although at times they might appear to run counter to the experience we had had or received second-hand, we must give fair and just criticism and a fair hearing to what he had to say on the matter; for he, and he alone, had made practical trials with it. When he tackled it he first of all gathered evidence with regard to the horse and ass cross in the breeding of mules. This was a case in which he could very easily obtain evidence, especially in South America. Curiously enough, many breeders there had the idea that if they went on breeding mules from mares the latter gradually became more and more sterile; and so they made a practice of taking not more than three mules from the same mare before going on with horse-breeding from her again. Yet they had men saying they never saw an instance that would justify belief in telegony. In the west of Ireland, where they breed numerous ponies, it was said they had the same experience. It had not been found possible to repeat the mare and quagga experiment, as the quagga became extinct. The nearest approach to it was with the zebra. Professor Ewart crossed this animal with something like 30 mares of different colors, and from these mares he got 13 hybrids, and 20 subsequent foals from mares that had bred hybrids. Of the 20 foals only three showed any signs or marks whatever of the zebra. When he had experimented for some years he thought he had established a case of telegony. Markings appeared at the back of the legs and elsewhere on the foals, but these disappeared as soon as the animal dropped the foal's coat. West Highland mares, pure bred, which had never seen a zebra, had pure foals which had just the same stripes, but these persisted after the foal's coat was shed. Similar experiments were carried on on a large scale in Brazil, and negative results were obtained in every case. Herbert Spencer said telegony could not be obtained except it occurred in an extreme cross. Others again said they could not get it in the extreme cross. This was tried in the case of a mare and different stallions, and there

was not the slightest evidence, in color or otherwise, of the influence of any sire on the foals that followed by other sires. The same result followed in the case of pure-bred donkeys. It was also related that a horse called Colonel was mated with a pure-bred mare, Actaeon, and that most of Actaeon's subsequent foals bore traces of Colonel. Yet when this was carried out experimentally the case broke down entirely. In the case of dogs the belief in telegony seemed strong, but exhaustive experiments which had been carried out failed to establish the theory. He related several instances in which careful tests had been made. At the present time popular opinion was still in favor of telegony, and he was aware that some of the members of the branch might have cases in their mind that might make them think what he had been saying was contrary to the weight of evidence, but they must bear in mind that they must be absolutely positive of the purity of the strain of breed they were dealing with, and that knowledge was not so easily obtainable with the types at present existing. They must work that down to proof positive before they could be certain, and they must have control experiments.

Naracoorte, August 10.

(Average annual rainfall, 22in.)

PRESENT.—Messrs. L. Wright (chair), W. Loller, E. Coe, A. Langeludecke, jun., C. Bray, W. E. Rogers, A. Caldwell, F. H. Holmes, J. M. Wray, and S. H. Schinckel (Hon. Sec.).

CO-OPERATIVE WOOL DEPOTS.—A lengthy discussion of this subject occurred at this meeting and also at the July meeting. [Owing to lack of space the very lengthy reports published in the South-East papers cannot be reprinted here, and it would not be fair to those who are for or against the proposal to attempt to condense the statements put forward. Possibly the Branch may be able to discuss the matter with the Wool Expert at a future meeting, when many points of misunderstanding will be cleared up and a valuable report of the proceedings be published in this *Journal*.—ED.]

THE JOURNAL OF AGRICULTURE

Published Monthly.

Subscription, 1s. per annum to residents in South Australia, and 2s. 6d. per annum elsewhere, including postage.

Circulation, 6,000 Monthly.

THE Journal contains information of an official character relating to the Agricultural Lands, Stock, and Produce Export Departments. Illustrated articles and paragraphs by Government experts dealing with all branches of agriculture, horticulture, viticulture, pastoral matters, dairying, stock diseases, poultry, etc., are published regularly.

The results of experiments in connection with methods of agriculture, etc., stock and poultry diseases, insect and fungoid pests in South Australia and other lands are recorded, as well as the results of work at Roseworthy Agricultural College.

The experience of members of the Agricultural Bureau is made available to subscribers by the publication of reports of meetings of the Branches, including the more important papers and the discussion on them.

The Inquiry Department of the Journal furnishes replies by Government experts to all questions sent in, and advice is given to beginners in agricultural industries.

The Reference Library of the Department of Agriculture, which contains so many valuable works on agricultural subjects and thousands of bulletins issued by Departments of Intelligence in all parts of the world, is at the disposal of subscribers during office hours.

Applications for enrolment on the subscribers' list should be addressed to the Department of Agriculture, Victoria Buildings, Victoria Square, Adelaide.

POINTS FOR PRODUCERS.

Profitable Longevity of Dairy Cows.

Probably the majority of dairy cattle are rejected from the herd on account of failure to breed, or from udder trouble, before the effect of advancing years can be observed to any marked extent. It is a fact often observed that a cow may make her best record when 10 or 11 years old, although as a rule she does her best rather earlier. If a dairy cow continues to breed she usually shows no marked decline until at least 12 years old. Occasionally a cow continues to breed until she is 16 or 18 years old. While it is not entirely safe to judge the future milk production of a cow from her two-year-old record, it is reasonably safe to judge the richness of her milk. A dairy cow on the average as a two-year-old may be expected to produce about 70 per cent. ; as a three-year-old, around 80 per cent. ; and as a four-year-old, about 90 per cent. of the milk and butter-fat she will produce under the same treatment when mature. The richness of the milk remains practically constant from year to year, except that after the third milking period there is a slow gradual decline with advancing years.

The Pollination Question.

Careful experimentation, writes the author of a bulletin issued by the Oregon Agricultural College, has shown that very little, if any, pollen of the fruit trees, other than nut trees, is transported by the wind. Probably 99 per cent. or more of the transfer of pollen is done by insects. Prime among these may be mentioned the honey bee. Bumble bees, ants, flies, moths, and short-tongued bees play an important part. However, there is no doubt but that the common hive bee is by far the best of all, and it will pay every orchardist to have a few stands among his trees.

Hen Manure with Chemical Fertilisers.

On an average, hen manure is worth about four times as much, pound for pound, as horse manure. The plan of handling it economically is to keep it very dry and pulverise it and use alone or mixed with chemicals. Sifted coal ashes, road dust, land plaster, or ground phosphate rock are all good to dry out the manure. They should be sifted freely under the perches.

Clean these perches frequently and pack the manure under cover in a dry place, sifting the drying material over it. It will be found later in dry hard chunks. These are crushed with a heavy spade or maul and the crushed manure sifted through a screen. Then it can be broadcast or scattered in the hill as it stands. A better way to get its full value is to mix it with chemicals, say, 1,000lbs. manure, 150lbs. nitrate of soda, 600lbs. fine bone, and 250lbs. muriate of potash, or small quantities in the same proportion. This gives a good fertiliser for any crop. Do not mix hen manure with wood ashes.—*Rural New Yorker*.

Treating Farmyard Manure.

When farmyard manure is ploughed in the land there is far less waste of its valuable constituents than when exposed in heaps for some time to the air and rainfall, which causes loss by fermentation and drainage of the nitrogen, ammonia, &c. The manure in the latter case will not pay for the litter that it has absorbed or the labor that it has incurred. On the other hand, when it is ploughed in soon, the manure becomes incorporated with the soil, and its effect on the latter and subsequent growth of the crop is far more advantageous. Farm manure which has been properly treated in covered yards, free from oxidation and excessive moisture, carted on to the land in this condition is almost (if not quite) as efficacious as when folded and subsequently ploughed under. The time must be passing by when heaps of dung, weighted with sodden straw (or litter of any kind), were collected from open yards and left in a heap in the corner of a field till absolutely worthless.—*Agricultural Gazette*.

English Live Stock Returns.

The preliminary statement of the agricultural returns for England and Wales, collected in June last, show decreases among all species of animals. Horses used for agricultural purposes are fewer by 30,740, but "other horses" (apart from unbroken horses) show an increase of 21,094. Separate returns under the 'atter head were first collected in 1911, and it is probable that some of the horses comprised within this category may previously have been returned as agricultural horses. Cattle have declined by 72,339, of which 44,818 were cows and heifers in milk or in calf. Sheep declined by over 1½ millions, or 6.6 per cent., the greatest relative decline being among those (other than ewes) aged one year and above. Pigs declined by 154,681, or 5.8 per cent., the decrease in the case of breeding sows being 41,514, or 11.1 per cent.

Spreading Lime with a Broom.

The question of using lime on our land, says the *Rural New Yorker*, is being agitated more and more at the present time. Farmers who have never used it before are buying in small quantities—from 2 to 5 tons. Unless one possesses a fertiliser to drill the work of putting it on becomes a problem. Of course, throwing it on by hand is out of the question, as its caustic nature would soon put one's hand out of commission, to say nothing of the discomfort it would cause to the respiratory organs. I have devised a plan for spreading it which is simple and effective. Put about 10 bags in a lumber wagon, have a man to drive the team, remove the tailboard, dump out one bag at a time in the back of the wagon; then, after having tied a large sized handkerchief over nose and mouth to keep out dust from lungs, take a common house broom and sweep out the lime a little at a time, first on the left, then on the right, and straight behind. In this way a 10ft. wide strip can be covered as fast as the team can walk. A ton an hour can be put out by this means.

Gypsum on Cow Manure.

To prevent flies from breeding in manure heaps, several of the large dairies in California use nothing but ground gypsum. One dairy uses a large quantity. They have over 100 head of stock continually housed, and claim that there is absolutely no odor, nor will flies go near it. All that is necessary to do is to sprinkle a small portion of this dust at the back of the stalls and on the manure pit.

Independence which is a Handicap.

There is such a thing as making a farce of this so-called "independence" of the farmer, says *Hoard's Dairyman*. Only a few years ago every farmer in Wisconsin was very independently making his own butter—or his wife was—and swapping it at the store for codfish, calico, and what not, and he thought he was doing very well if he got 15 cents a pound in trade for it. Every batch of butter had its own independent flavor. All this has been changed. Farmers dropped their lofty notions of making independent butter and came together in co-operation, and took their milk to a creamery, where good butter saleable for cash was made. See how the consumption and price of butter have increased under co-operation. Just as the farmer ceased to be foolishly independent did he become more prosperous, for his milk gave forth better butter. This is what co-operation has done with butter. There is such a thing as having a poverty-stricken independence.

Farming College on Wheels.

More than 102,000 California farmers attended the lectures of the University of California professors and visited the Southern Pacific agricultural demonstration train during the 1911-12 season, just ended. The precise number of auditors at these lectures was 102,624, according to a careful census taken at each stop of the train. This is an increase of 24,400, or 31 per cent., over the attendance of last year. Close to 5,000 miles were covered by the train during the 1911-12 season—more than twice the distance covered in 1908. There was a noted increase in attendance at practically every place visited. In only a few instances did the attendance show decrease, and in all cases it was caused by inclement weather. This was the fourth year of the agricultural and horticultural demonstration trains, and greater attention was given to actual instruction work. The cars were arranged so that persons interested in any one of the subjects exhibited could visit that car in particular, listen to the lecture of the specialist in charge of the car, and ask as many questions about the subject as they saw fit. Discussion was invited, and through such disputation many important and interesting facts were made clear to all producers.—*Pacific Rural Press*.

Apples in the United States.

The Bureau of the Census reports that on April 15th, 1910, there were 151,323,000 apple trees of bearing age, and 65,792,000 trees of non-bearing age in the United States. The production of apples in 1909 was 147,522,000 bushels, valued at \$83,231,000. According to the census of 1900 there were 201,794,000 trees reported June 1st, 1900, and the production of apples in 1899 was 175,397,000 bush. Only about 10 per cent. of the apples produced in this country are exported. They represent the very highest qualities in fresh fruit—about \$5,300,000 worth on an average for the past two years, and 45,000,000 lbs. of dried apple exports last year, worth \$3,850,000.—*Californian Fruitgrower*.

Efficacy of Fertilisers on Soils Relatively Rich.

Can fertilisers be profitably employed on soils which, by chemical analysis, are shown to contain a total sufficient supply of plant foods? Theoretically it would be thought that if the soil is naturally so rich, the application of more plant foods would be an unnecessary expenditure, but in practice the result works out differently; and this apparent paradox arises from the fact that much of the plant food, shown by analysis as present in the soil, is not in an available condition. This applies especially to applications of phosphate of lime and potash.

Foot and Mouth Disease.

Thirteen separate centres of foot and mouth disease have come to light in the United Kingdom since the outbreak in Cumberland on June 24th last, and the total number of outbreaks confirmed up to September 9th was 75, distributed as follows :—Chester, 7 outbreaks ; Cumberland, 3 ; Durham, 1 ; Flint, 1 ; Hampshire, 1 ; Lancashire, 8 ; Leicester, 3 ; Northumberland, 28 ; Salop, 1 ; Somerset, 2 ; Staffs, 1 ; Surrey, 1 ; Sussex (East), 4 ; Yorkshire (East Riding), 2 ; Yorkshire (West Riding), 12.

Powder for Plant Food.

The United States Army and Navy Departments, says the *Pacific Rural Press*, find themselves with millions of pounds of obsolescent powder on hand which cost half a dollar a pound—too expensive, they conclude, to be dumped into the sea, as has been the custom with cheaper grades in the past. They have, therefore, called on the Department of Agriculture to help them out, and Dr. B. T. Galloway, Chief of the Bureau of Plant Industry, has made some exhaustive experiments with the powder as a fertiliser, which promises to relieve the fighting department of their accumulation of obsolete explosives, composed largely of nitrogen, as are all high explosives. Some way has yet to be found to treat the powder to make it profitable financially as a fertiliser, but the experiments thus far have proved its value for that purpose, and the proper way of treating it to make possible its distribution, it is expected, will shortly be found.

Imports and Exports of Plants.

During the month of October 8,168bush. of fresh fruits, 5,220 bags of potatoes, 1,366 bags of onions, 59pkgs. of plants, and 20pkgs. of vegetables were examined and admitted at Adelaide and Port Adelaide under the Vine, Fruit, and Vegetable Protection Act of 1885 ; 632bush. of bananas (chiefly over-ripe) and 1pkg. of plants were rejected. Under the Federal Commerce Act 544 cases of fresh fruit, 4,215pkgs. of dried fruit, 29pkgs. of preserved fruit, 2pkgs. of honey, and 911pkgs. of plants and seeds were exported to oversea markets during the same period. These were distributed as follows :—For London, 2,282pkgs. of dried fruit, 910pkgs. seeds, and 2pkgs. honey ; for South Africa, 130pkgs. dried fruit ; for Canada, 741pkgs. dried fruit ; for India and East, 120 cases apples, 29pkgs. preserved fruit, and 7pkgs. dried fruit ; for New Zealand, 424 cases citrus fruit, 1,055pkgs. dried fruit, and 1pkg. of plants. Under the Federal Quarantine Act 1,395pkgs. of plants, seeds, bulbs, &c., were examined and introduced from oversea markets.

INQUIRY DEPARTMENT.

Any questions relating to methods of agriculture, horticulture, viticulture, dairying, &c., diseases of stock and poultry, insect and fungoid pests, the export of produce, and similar subjects, will be referred to the Government experts, and replies will be published in these pages for the benefit of producers generally. The name and address of the inquirer must accompany each question. Inquiries received from the question-boxes established by Branches of the Agricultural Bureau will be similarly dealt with. All correspondence should be addressed to "The Editor, *The Journal of Agriculture*, Adelaide."

"W. R. S." asks which takes most out of the soil in a wheat paddock, cutting the crop for hay or taking it off with the stripper as a grain crop?

Reply—In a warm, dry climate the wheat plant ceases to take nutriment from the ground soon after flowering. So far as depletion of essential minerals is concerned it is, therefore, immaterial whether the crop be removed after that stage as hay or as grain and straw. If the straw is left standing after stripping, to be ultimately incorporated with the soil, about 20 per cent. of the nitrogen and 30 per cent. of the phosphoric acid (about 50lbs. supers. to the acre) will be restored, in addition to the organic matter of the straw, which will form humus. If the straw is burned off, the 20 per cent. of nitrogen will be lost, and, of course, the organic matter.

TREATMENT OF ORANGE TREES.

"S. R. C.," East Adelaide, asks for advice in regard to his orange trees, which some 10 weeks ago blossomed very freely, but when the blossom fell off the leaves from the top branches also fell off, and the branches commenced to die.

Reply—Mr. G. Quinn, Horticultural Instructor, writes—"From the description of the orange trees I imagine there is something affecting their roots, as the symptoms of leaf-shedding and dying of the tips of the shoots indicate this. If the subsoil happens to be a stiff clay, the terminal roots have most likely decayed during the past winter, and the evidence was only manifested when the strain of blossoming came. I would suggest—to strike balance between the absorbing roots and the transpiring surface above ground—the tops be cut back some little distance below the declining shoots. Keep the soil loose around the tree over the spread of roots and water sparingly until growth begins, after which the water may be increased. Apply the water in rings made just about as wide as the spread of the foliage, putting

about 4ozs. to 8ozs. sulphate of ammonia in the ring before watering. When the watered soil loses its stickiness, break up the trenches and pulverise the soil to an even surface. If you have any stable manure, put it an inch thick over the soil, covering just a little wider than the watered area with the mulch. Do not water on top of the mulch, but push it away each time and replace it again."

"M. B.," Sandy Creek, asks what is the right quantity of potash to apply to orange trees.

Reply—Mr. Quinn writes—"Potash is considered a most important factor in determining the quality of the fruit of the orange. Sulphate is the best form in which to apply it to trees of a bearing age. Use from $\frac{1}{2}$ lb. to $1\frac{1}{2}$ lbs. per tree, according to size. It is usually dug in around the trees, extending a little beyond the spread of the foliage in early winter. As the season is now advanced, I would suggest, if you irrigate, putting it in the rings and washing it into the soil as soon as convenient. If not utilised by the trees directly it will not be lost, as it does not leach out of the land. If your orangery is on sandy soil it is almost certain to be deficient in potash. Sulphate of potash usually costs about 14s. to 15s. per hundredweight in Adelaide, and contains about 52 per cent. of actual potash."

FEED FOR CHICKENS.

"C. C. C." asks if it is advisable to give raw meat to chickens, and for a remedy for scaly leg.

Reply—It is inadvisable to give raw meat to chickens. You may dig up damp ground and give them earthworms. Toe picking is occasionally seen among chickens, and sometimes a weak one may be pecked and eaten. You must watch them, and any which are being pecked must be removed until the sore has healed.

Scaly leg.—Scrub the legs with a stiff brush and hot soapy water. Dry well and then smear liberally with soft soap. A second application in a fortnight may be necessary.

WHEN TO SOW LUCERNE AND SORGHUM.

"A. M. P." asks the best time to sow lucerne and sorghum seed in the district of Hookina.

Reply.—Sow lucerne in the autumn, during March, April, or May, as soon as you get a good rain to put the land in condition. In the northern areas, where the land sets very hard under the hot weather, as lucerne is a delicate plant at the start, it is generally found that sowing in the autumn in a good season before the weather gets cold, on land that has been cleaned by good fallowing, succeeds better than spring sowing. In the south spring sowing is to be preferred. Sorghum should be sown at the end of September and during the first half of October.

STOCK INQUIRIES.

(Replies supplied by Mr. F. E. PLACE, M.R.C.V.S., B.V.Sc., Veterinary Lecturer.)

"G. H. P.," Karoonda Bore, Brown's Well, has a young horse, rising 5, which suffers from a soft swelling between his front legs; the swelling disappears on exercise or being at grass. Other horses have had similar swellings in various parts of the body, such as breast and sheath, which disappear in a few days on being turned out. Another horse coughs and is very distressed at work, heaves at flanks, &c. He asks for advice.

Reply --The trouble here is lymphadenitis, a disease similar to strangles. The inquirer points out the treatment, namely, rest and green feed. As a preventive half an ounce of flowers of sulphur may be given once daily for a fortnight in a little chaff or bran. One or two ounces of hyposulphite of soda in drinking water once or twice daily for a few days is useful when the disease is on. In the case of the horse that is distressed, the disease has spread to the lungs. Work should be avoided altogether in such cases, as most dangerous inflammation of the lungs often follows it.

"A. J. H.," Mount Gambier, has a four-year-old mare which was bred in a swampy place and lived there till 3 years, when she was broken in. She often goes very lame after work, but recovers after rest. Sometimes the lameness will work off and recur on the same journey. She is worse in winter. He asks the cause of the trouble.

Reply—It is quite impossible to give an opinion of value on the symptoms described, but from the history it is probable that the mare suffers from injuries to the blood vessels caused by worms. She may become worse at any time, and it is not advisable to depend upon her growing out of her trouble. Treatment which might improve her would be half an ounce of Fowler's solution of arsenic in her food twice daily for a fortnight, and then once every other day for 10 times more.

HERD OF WHITE CATTLE.

LEAF SCORCH DISEASE OF CELERY.

By T. G. B. OSBORN, M.Sc., Professor of Botany and Vegetable Pathologist,
Adelaide University.

The celery "leaf scorch" (also known as "leaf spot," and in the United States as "late blight") is a disease that has only comparatively recently come into notice, either in the United States of America or in Europe. In the last two years it has become widespread in the United Kingdom, and a full account of the disease was published last year in England*. In July last the South Australian Department of Agriculture received celery leaves affected with leaf scorch from Mount Gambier. The grower stated that his crop had been

Fig. 1.—Celery Leaf infected with *Septoria Petroselinii*, Desm. var. *Apii* Br. and Cav.
Pycnidia of the fungus are visible on the leaflets and on the stem. Natural size.

ruined for the last two or three years by the disease. It has therefore been thought advisable to publish a short account of leaf scorch for the information of other growers.

Celery leaf scorch is caused by a fungus known as *Septoria Petroselinii*, Desm. var. *apii*, Br. & Cav. The typical form of this fungus (*S. Petroselinii*)

* Chittenden, F. J. "Leaf Spot of Celery." Journ. Roy. Hort. Soc. (London),
vol. 37, p. 115. 1911.

occurs on parsley, but it has not yet been recorded for the State. Other members of this genus attack the leaves of pears, carnations, raspberries or blackberries, and wheat, and have been found on the last four plants within this State.

APPEARANCE OF THE DISEASE.

In the case of celery plants, small scattered yellowish patches, rapidly becoming brown, appear on the leaf. These are irregular in shape, and if conditions are favorable to the growth of the fungus the whole leaf may be affected. The withered brown appearance it then presents has given rise to the popular name of "leaf scorch." Such a destruction of the leaves checks the growth of the head, and may result in a general wilting of the plant. Soon after the spots on the leaf turn brown the fructifications of the fungus become visible as numerous minute black spots dotted over the brown area (fig. 1.) The warm, damp days of the late autumn in England are most favorable to the growth of the fungus, and it may spread along

Fig. 2. - Magnified view of portion of infected celery leaf stalk, showing pycnidia. $\times 10$.

whole rows of celery with great rapidity. In the United States the chief harm is done to celery plants in the early autumn, though a few spots of the disease may be present at any time during the summer. In that country, where it is usual to lift the crop early and store the heads, much of the damage occurs in the store, especially if the ventilation is defective.

DESCRIPTION OF THE FUNGUS.

If a diseased portion of the leaf or stalk be examined with a magnifying glass the fructification is seen to have the appearance shown in fig. 2. Each of the black dots or fruit bodies (*pycnidia*) is composed of a dark-brown mass of fungus cells (*hyphae*) closely interwoven to form a flask-shaped receptacle (fig. 3), and imbedded in the tissue of the plant. The neck of the flask is open and projects above the surface of the plant. All round the inside walls of the flask are the fungus cells on which the reproductive spores are formed. The spores are long but very narrow, being almost needle-shaped, only they are often slightly curved. A high power of the microscope shows them to be composed of five or six cells (fig. 4). The spores are produced in countless

numbers inside each flask-shaped pycnidium, and escape through the open mouth to the surface of the leaf in the form of a thread. There, in drops of water or by air currents, these are borne to fresh leaves which they infect.

METHODS OF DISTRIBUTION.

Rapid dissemination of the disease occurs by means of the spores described above. The fungus exists in a dried up condition from season to season on

Fig. 3.—Section of celery leaf passing through a pycnidium, showing the flask-shaped fruit body embedded in the leaf tissue and containing numerous spores. Highly magnified.

any dead leaves or stalks that may be left about the celery beds. It retains its vitality for some time under these conditions. The spores germinate when there is sufficient moisture and infect the next crop of young celery plants. The presence about the celery beds of dead leaves or stalks from the previous year's crop may account for a recurrence of the disease; but crops grown in fresh ground could seldom be infected in this manner. It has been shown by Mr. Chittenden that the seed sown is frequently infected, and may be the cause of a fresh outbreak. His observations have been confirmed by an

Fig. 4.—Spores of the celery leaf scorch fungus. Very highly magnified.

Fig. 5.—Celery "seed" and fruit-stalk showing pycnidia of the leaf scorch fungus. By sowing such seed a fresh infection of the new crop is almost sure to result. Magnified 10.

examination of seed in this State. Celery "seed" is really the small fruit of the celery plant, the true seed being enclosed within it. The fungus attacks the fruit walls and the small stalks upon which the fruits are borne, as it does all other green parts of the plant, and produces its fructifications upon them. A few celery seeds taken from a sample sent from Mount Gambier and obtained by the grower from a reputable seedsman, will illustrate this

(fig. 5). In the figure the larger black spots seen upon the three seeds and stalk represent pycnidia of the fungus. These are common upon the fruit stalks, but not so common on the fruit itself. Thus the sowing of fresh seed may even cause a recurrence of the disease upon the next season's crop.

TREATMENT.

The field treatment that has been recommended is to spray with dilute Bordeaux mixture, or with a solution of potassium sulphide, 1oz. to 3galls. of water.

In the store special attention should be paid to ventilation and dryness.

The refuse from an infected crop should be gathered up and burnt, and not merely thrown on the rubbish heap.

If possible seed should be purchased which is clean and shows no sign of the fungus. Samples that show many pieces of fruit stalks or small withered seeds should be avoided.

FARM ANIMALS.

HEREDITARY UNSOUNDNESS (*Continued*).

By C. A. LOXTON, G.M.V.C., Assistant G.V.S.

BONE SPAVIN.

This disease is the most frequent and most serious of those affecting the hock, and occurs as a deposit of bone on the inner and lower portion of the joint. The hock joint is a very complex one, consisting of an upper portion, which, with the bone of the leg (*tibia*), helps to form the true hock joint, and is where the principal movement of the hock takes place; the lower portion of the hock is made up of four small bones, having gliding surfaces between them, and rests on the top of the cannon bone. It is the inner aspect of the bones forming the lower portion of the hock which is implicated in bone spavin, the bony deposit taking place both between the bones and on the internal surface of the joint forming the enlargement known as a spavin. This deposit of bone obliterates the gliding surfaces between the small bones already spoken of and causes stiffness and want of proper freedom of flexion of the hock.

Spavin is seen most frequently in light horses, more especially those with weak badly-formed hocks. Any defect in the conformation of the joint acts as a predisposing cause, all forms of defective hock being liable to the disease. The complicated mechanism of the joint is in itself a predisposing factor, and this tendency is greatly increased if any weakness is present owing to defective conformation.

Apart altogether from predisposition due to defective conformation, heredity plays a strong part, for it is well known that certain families with well-formed hocks have a tendency to become affected with spavin. The occurrence of the disease in young animals which have done no work also points to hereditary predisposition. As a rule one hock only is affected, but occasionally the disease is seen in both. The visible enlargement varies in size and position, and the extent of the lameness is not in proportion to the size of the bony deposit; in fact, characteristic spavin lameness is sometimes seen without any visible alteration in the joint—occult spavin. However, spavins in a forward position usually cause a more severe lameness, and in some cases render the subject a permanent cripple.

SYMPTOMS.

When a spavin is of any size it can be seen by standing in front of the horse and viewing the hocks from between the forelegs and comparing the internal contour of the joints. The sense of touch is also of considerable value in detecting spavin, but both skill and practice are necessary. When at rest the animal stands with the affected leg forward, the heel raised and the hock flexed. When made to "stand over," weakness is shown by the quick jerking movement of the affected leg; this is also seen by turning him sharply in his own length. Lameness is increased by turning the horse in a short circle, turning towards the sound side.

Spavin lameness is most pronounced when the horse is first taken out of the stable and wears off with work, but appears again after a rest. The action is marked by stiffness of the affected leg and want of freedom in hock flexion. Sometimes pain is shown by forcible flexion of the joint, but the leg should be grasped by the cannon, as any disease of the lower joints might lead to a wrong opinion should the leg be raised by holding up the foot.

The disease develops slowly, and sometimes lameness is present before any change can be detected in the joint. Once the process of the disease is complete, and the affected bones are firmly cemented together, the acute symptoms of lameness may disappear, but there will always be a noticeable want of hock flexion shown by the wear of the shoe at the toe.

Local heat and pain at the seat of the disease may or may not be present.

In breeding special attention should be paid to this form of hereditary unsoundness. Avoid breeding from stock affected with the disease, and from those with any defective conformation of the hock.

A DESTRUCTIVE ROOT MITE.

The failure of some French beans to germinate at Mount Barker led to investigations being made as to the nature of some small mites which were found in large numbers upon the beans. They were submitted to Mr. A. M. Lee, the Entomologist at the Adelaide Museum, who at once recognised them as the "bulb mite" (*Rhizoglyphus echinopus*), a name meaning "spiny-legged root eater."

The mite is very small, and a good magnifying glass is needed to see it at all clearly. It is almost transparent, but slightly brown at the head. Mr. Lee says that the pest occurs in many parts of the world and attacks a multitude of plants. Stored onions and bulbs are frequently attacked and seriously injured. When attacked they appear to be covered with a kind of greasy dust, this being due to the bodies of the mites and their droppings. When the mite appears it is generally in enormous numbers. Some seedlings are attacked as soon as they commence to grow, with the consequence that they just break through the ground and die; or they may not even break the ground before dying. The mite is sometimes the real cause of the apparent failure of seeds to germinate. Carrots are sometimes attacked just where the leaves join the carrot itself, and in consequence the leaves fall off and the carrot commences to rot and hollow out. Cuttings when put into the ground will often not root on account of this pest, and an examination will show that the bark has rotted and is swarming with mites. The mites seem to prefer to attack plants which have been injured in some way, or which are growing under unhealthy conditions. With fruit trees the pest usually appears only after the roots have been injured by cultivation, or weakened by the attacks of fungi or insects. When once it appears, however, the plant attacked is nearly always doomed.

When the roots of the apple are attacked the bark of the root softens and readily tears off, and on examination is seen to be swarming with the mites in places; and small roots do not grow on the attacked parts. The trunk a few inches above ground is also sometimes attacked, the mites seeming to work upwards from the rotting roots. Sulphur will prevent the mites attacking stored bulbs and cuttings, but once they have gained access to the roots nothing economically practicable can be done against them.

THE VALUE OF BIRDS TO MAN.

PROTECTION AND PRESERVATION URGED.

In a paper entitled "The Value of Birds to Man" which was read at a meeting of the British Empire Naturalists' Association, Mr. James Buckland puts forward a strong plea for the protection and preservation of bird life. The author deals with his subject in a comprehensive manner. His paper is too long to permit of reproduction in the *Journal*, but the following extracts should afford food for reflection :—

"Vegetation is the prime requisite for the perpetuity of all other forms of life upon the earth. It is the only form in organic nature that does not war upon other forms. The greatest known enemy to vegetation is insect life, while bird life, by virtue of its predominating insect diet, wields a most important balance of power against the ravages of this chief pest of vegetation.

"This is the principal mission of the bird in preserving the balance of nature's forces; and when we remember that birds are distinguished from all other animals by organs of perfect flight, when we remember that the sense of sight in birds is developed to a degree unparalleled in the animal world, when we remember the surpassing breathing power possessed by birds, their wonderful muscular strength and activity, the high temperature and rapid circulation of their blood, and, as necessary fuel for all these fires, their extraordinary capacity for assimilating food, we must admit that these marvellous creatures are admirably fitted to pursue and capture their natural prey, or, by making earth-wide sweeps from zone to zone, to follow the seasonal ebb and flow of the tide of insect life.

NUMBER AND REPRODUCTIVENESS OF INSECTS.

"The number of insect species is greater by far than that of the species of all other living creatures combined. Over 300,000 have been described, and it is considered not improbable that twice that number remain to be described. Practically all living animals, as well as most plants, furnish food for these innumerable hordes.

"The fecundity of certain insect forms is astounding, the numbers bred reaching such prodigious proportions as to be almost beyond belief. Riley once computed that the hop aphid, developing 13 generations in a single year,

would, if unchecked to the end of the twelfth generation, have multiplied to the inconceivable number of ten sextillions of individuals. Noting the preceding, Forbush says if this brood were marshalled into line, 10 to the inch, it would extend to a point so sunk in the profundity of space that light from the head of the procession travelling at the rate of 184,000 miles per second would require 2,500 years in which to reach the earth.

"Kirkland has computed that one pair of gipsy moths, if unchecked, would produce enough progeny in eight years to destroy all the foliage in the United States. A Canadian entomologist has determined that a single pair of Colorado beetles, without check, would multiply in one season to 60,000,000 units.

"The voracity of insect life is as astonishing as its power of reproduction. Many caterpillars consume twice their weight in leaves per day, which corresponds to a horse eating daily a ton of hay.

"The development of young birds is so rapid and the demand upon the vitality of the older ones so great that an enormous amount of food is necessary to sustain the vital processes. The number of insects daily passed into the insatiable maws of the nestlings almost exceeds belief. But the most valuable services of the adult bird are rendered when it is feeding in winter or early spring, for then it destroys countless numbers of insects in the embryo state, and thus prevents myriads of depredators from coming forth.

"Grave and far-reaching results invariably follow the suppression of this perennial regulative influence which is exerted by birds individually everywhere as a check on insect life."

CHECKING INSECT IRRUPTIONS.

Instances in support of this statement are then given, and the paper proceeds:—"In the early days of the colonisation of New Zealand swarms of caterpillars infested the open tussock-clad country. When the white man began to cultivate the land this caterpillar disappeared from its old haunts and attacked the English grasses and cereal crops, increasing so enormously in numbers by reason of a more favorable environment that they quickly became a blasting plague. They came not singly, or even in battalions, but in mighty armies which laid waste the land. I have seen regiments of this invading force cover the pastures in such numbers as to make the green one brown. I have seen them march out of one cornfield—having stripped every stalk bare—cross the road in solid phalanx and pass into another. I have seen big mobs of sheep mustered in hot haste and driven backwards and forwards to crush the atoms with their hurrying feet. I have seen every available horse-roller in a district brought up hurriedly, like engines to a fire, and dragged to and fro over the crawling masses until the huge cylinders stuck fast in the mire of crushed insects. I have seen large ditches dug to

stop the invaders' progress. The efforts were as futile as that of a child who builds a bank of sand by the sea, thinking it will stem the oncoming tide. Even railway trains were brought to a standstill, the wheels of the engine being unable to grip the rails owing to the countless hordes of caterpillars which were crossing the line. In time it became clear that if this disastrous condition continued it would be useless to attempt to carry on agriculture in New Zealand. Realising that any attempt which they might make to rid the smitten land of the plague would be but a mockery, the farmers turned their eyes longingly to the natural enemy of the caterpillar—the bird.

“Therefore insectivorous birds from the old country were introduced, and the one that multiplied most rapidly was the sparrow. And the sparrow soon cut short the career of the caterpillars.

“That formidable imported weed, the variegated Scotch thistle threatened to overrun the whole of New Zealand. Where it had once fairly established itself it seemed impossible to eradicate it; and it was spreading with the speed of scandal. . . . But the sparrows took to eating the seed. In tens of thousands they fed on it, giving it a preference to all other hard food, and the weed was conquered.

“To-day, in New Zealand, the sparrow is looked upon as an impudent thief, without a redeeming feature in its character. No one, of course, can say what would happen if the sparrow was dismissed from New Zealand, but it is certain that the Dominion would be again overrun with caterpillars and thistles.

“In Australia a plague of grasshoppers periodically visits the paddocks to devour the crops. But the ruin they would otherwise bring on the farmer is checked by large flocks of glossy ibises, spoonbills, cranes, and other native birds. It has been computed by an eminent naturalist that a flock of 200,000 of these saviours will consume in a single day 25 tons of grasshoppers.”

THE VALUE OF THE BIRD IN THE ORCHARD.

On this phase of his subject Mr. Buckland states:—“For man's purposes the work of the bird in the orchard is not so thorough as that done by them in the forest. Birds are the slaves of nature, and in the main nature's endeavors are put forth only to produce such fruits as will ensure the perpetuity of each species of tree. With man the case is altogether different. His main object is not the propagation of trees, but the production of a giant gooseberry. Moreover, by introducing arsenical spraying, tarred and greased bands, and other devices to counteract the evil action of insects, he has to a certain extent taken upon himself the office of the bird. In this he is wise, for it must be admitted that if he wishes a large crop of fruit he must himself prevent the inroads of those insects which attack the fruit directly. It cannot be expected of the bird that it will become an efficient ally of man in

protecting the artificially produced fruit from the attacks of the numerous insects that are drawn to the orchard by a vastly increased quantity of fruit of a vastly better quality than the natural product. For all that, fruitgrowers are largely indebted to the bird for a great part of their annual crop. There are a host of tiny creatures that are not affected by spraying. These lili-pitian pests are the plant lice and their allies, bark lice, and scale insects. Usually their presence is unnoticed on account of their diminutive size; but they suck out the juices of the tree and are exceedingly harmful. If their multiplication remained unchecked the ultimate result upon the development of the fruit, if not upon the life of the tree, would be very great. But nothing, however small, escapes the prying eyes of a bird, and it clears the trunk branches and twigs of these encumbrances.

"Birds are charged, as though the case were one of theft, with feeding to a greater or less extent on the fruit which they help to produce. In Nature such services as the bird renders in direct protection of the tree is placed to its credit, and it receives its reward. Does man expect it, for his sake, to deviate from those habits which it has contracted under natural conditions? In other words, does he expect the bird to assist him in producing an unnatural surplus of fruit?

"Call the bird in the orchard an evil, if you will. But it is a necessary evil and the fruitgrower must make up his mind to pay the bird its wages, even though at times they may seem exorbitant.

"But let us suppose for a moment—though the supposition is absurd—that the modern fruitgrower could do without the services of the bird. Would that give him a right to slay it? Apart altogether from the agriculturist, what of the millions of people who, as an increment to their ordinary livelihood, grow fruit, but who cannot afford either the time or the money to treat their trees in the most approved and scientific way? What would happen to this poorer class of fruitgrowers if they were deprived of the services of the bird is best seen in what happened to Frederick the Great. This worthy, in a fit of passion, because a flock of sparrows had pecked at some of his cherries, ordered every small bird that could be searched out to be instantly killed. Within two years his cherry trees, though bare of fruit, were weighed down with a splendid crop of insects."

Among other questions dealt with by the author are: "The Value of Birds in Forests," "The Services of the Bird in the Garden," "Utility of Birds in the Meadow," "Value of Birds to Livestock," "The Bird as a Weed-destroyer," "The Bird as a Scavenger." The copy of the paper from which the extracts are taken was supplied by Mr. J. F. Mellor, of Fulham.

NAVEL ORANGES.

SALE IN ENGLAND.

The following special report, dated London, September 20th, has been received from the Trade Commissioner :—

Some few years ago I wrote at some length in regard to the prospect for the sale of Navel oranges in England. I then stated that, providing the quality was right and given proper supervision this end, it would be possible to realise as high as 20s. per case for a limited supply. Since writing the report referred to I have had the additional experience of personally selling thousands of cases of citrus and other fruits, not only to London buyers, but throughout the United Kingdom, and I am more than ever convinced that what I then affirmed can be put into actual effect. I stated a "limited quantity," because there are a certain number of shops in London and other large cities in the United Kingdom that have a class of customer who will buy fruit if it is attractive, and particularly if it is out of the ordinary season, no matter what the cost is ; but necessarily this class of buyer is limited. I have discussed the question of importing oranges with many large wholesale and retail buyers in the provinces, as well as London, and the consensus of opinion is that for any quantity up to, say, -1,000 cases of evenly-graded and well-packed medium-sized Navel oranges, if properly distributed, there would be sufficient demand to warrant asking from 15s. to 20s. per case ; but if we intend shipping larger quantities, say, 10,000 or 20,000 cases during the season, then we should of necessity have to take in the middle-class shops, and their purchasing power would be limited at from 12s. to 14s. .

My reason for again bringing the prospects of the market for this class of fruit before your notice is that I understand a further large area of land suitable for orange-growing is to be opened up on the river ; and it occurred to me that if a gross price of 12s. per case in England would pay, settlers could not do better than plant Navel oranges. I know that this price could have been obtained this season, and future conditions are not likely to be worse ; on the contrary, in the course of a few years, prices should be even better.

Apart from the improved purchasing power of the general public in England, there is to be considered that it is even more so in other countries. Take Germany as an instance. In 1880 the total population was 45,000,000, while in 1910 it was nearly 65,000,000, and is growing at the rate of about

900,000 per annum. I mention Germany in particular because it is one of the largest markets in the world for oranges, and statistics show that the consumption is annually increasing; and I think it is logical that as the German demand increases it will mean a less supply for England. I am aware that it has been stated by some of the growers in South Australia that a gross return of 12s. London is not a payable proposition to the grower, say, at Renmark. After all, I suppose the growers themselves should be better able to judge of what will pay them than I can be; but I may be allowed to suggest that probably when they have arrived at this conclusion they have been guided more by the price similar fruit has obtained on the local market than what would actually pay if grown in large quantities. Assuming that the freight to be 60s. per ton, 12s. gross London would mean not less than 8s. net Port Adelaide. In stating 12s. per case as my opinion of the lowest price we should obtain, I do so with every confidence, but subject to the following being strictly carried out:—

1. The growers should co-operate, in order that the number of marks should be reduced to a minimum, and the grading absolutely uniform.
2. The fruit should be shipped through one channel, to ensure proper distribution this end, as it would be fatal to the best interests of the growers if the whole of one shipment were placed on the London market only.
3. Shipments should be divided up as equally as possible, commencing in July, and the last shipment should reach London not later than the first week in October.
4. The most saleable sizes for a large quantity would be 72/80 per case.

Shipments arriving during the month specified would be certain to find ready sale, as the English markets are, with the exception of Cape oranges, quite bare of this class of fruit, the Continental fruit not commencing to come forward until the end of October. The principal sources of supply are Spain, Italy, and Turkey, with a comparatively small quantity from the United States. The total quantity of oranges imported into the United Kingdom last year was 259,000 tons, four-fifths of the whole being from Spain.

Last year 15,000 cases of oranges were imported from Cape Colony. The first shipment from that country usually arrives in London about the end of June, and the shipments continue until about the middle of September. During the past season ordinary Cape oranges have realised as high as from 15s. to 20s. per case.

Since writing the above I have had a chat with a representative of the Trade Commissioner of South Africa, and he gave me the following information, that may be of interest to you:—The standard cases of oranges from South Africa measure 12in. x 12in. x 26in. with centre partition. The oranges

from Cape ports are carried as ordinary cargo at 25s. per ton, while the oranges from the Natal ports are carried in cool chambers at 50s. per ton. Under the new mail contract, a copy of which I enclose, there is a reduction of 10s. per ton, providing the fruit is graded and passed by the Government inspectors, thus making the freight 40s. per ton for all Government inspected fruit. The last shipment of the season—800 cases of oranges—was put on the market last week, and realised the following prices :- Ninety-six to case, 17s. ; 126 to case, 18s. ; 150 to case, 18s. ; 176 to case, 19s. ; 252 to case, 20s. The average price for the season is, as near as possible, 12s.

NEW LIGHT ON LIME.

By J. B. MORMAN in *Country Gentleman*.

Every farmer knows from experience that sometimes the land needs an application of lime for its improvement, but for a long time neither science nor practice could give a satisfactory reason for this fact. Recently the beneficial action of lime has been recognised to be the result of physical, chemical, physiological, and bacteriological forces working in harmony.

The physical effects of liming were found to be dependent upon the character of the soil. An application of lime on heavy clay soils causes a flocculation of the fine particles and thereby materially improves the tilth, increases aeration, and facilitates the circulation of water. On light, sandy soils lime causes a reduction in porosity and thereby increases their water-holding capacity, limits oxidation processes, and favors bacterial activity.

The chemical effects of liming are mainly those dealing with the action of potash and phosphoric acid as essential plant foods. The action of lime in liberating potash from insoluble compounds is so pronounced that it has led many experts to regard lime as an indirect potash fertiliser. In like manner lime applied to soils that contain phosphorus in iron and aluminum compounds reacts with these substances in forming calcium phosphate—one of the most available forms of phosphoric fertilisers. Liming in such a case is

therefore regarded as an indirect application of phosphoric acid. Another chemical effect of lime is its neutralisation of acid substances which accumulate in soils as a direct result of the growth of crops and the decay of humus. If lime or other bases were not occasionally supplied to the land these acid substances would accumulate in such large quantities as to decrease production and render cultivation unprofitable.

BACTERIAL GROWTH INCREASED.

The chemical and physiological effects of liming are closely related. Acid conditions in soils not only diminish the supply of available plant food, but have a direct physiological effect on the plants themselves. Naturally this effect varies with the plant as well as with the form of the acid substance and the existing soil conditions. In neutralising such acid substances lime has a direct physiological effect on the plants. Furthermore, the relation of calcium to magnesium in the soils is of vital importance to the physiological functions in plants, so that by altering the calcium-magnesium normal ratio in soils through the application of lime plants may be benefited or injured to a greater or less extent.

The more recent development of the science of bacteriology has revealed the fact that there are many unsolved problems relating to the effects of lime on the growth and activities of soil bacteria. For the purpose of solving these problems the Iowa Experiment Station undertook a series of elaborate experiments on the bacteriological effects of liming. The branches studied related to the effects of lime on the increase or decrease of soil bacteria, on ammonification, nitrification, formation of nitrates, nitrogen fixation and denitrification in soils. The methods employed were virtually the same in each series of experiments, there being check samples and soils treated with lime at the rates of half a ton and one, two, and three tons an acre respectively. These amounts of lime were maintained in all the experiments reported. The conclusions reached as to the effects of lime on these different aspects of the problems may be summarised as follows:—Applications of lime in varying quantities increased the number of bacteria by a minimum of 75,000 to a maximum of 2,710,000 per gram of air-dry soil. The results of bacterial increase being considered as a whole, it was found that applications of ground limestone increased the bacteria in the soil rather uniformly. The larger the amount applied—up to three tons an acre—the greater the number of bacteria. On the other hand, a natural increase in the bacteria has a tendency to obscure the effects of liming, whereas a natural decrease makes them more pronounced. The actual number of organisms present in the same soil at different dates, when kept under greenhouse conditions, is exceedingly variable.

The experiments relating to ammonification, nitrification, formation of nitrates, and nitrogen fixation in soils had for their object the determination of the effects of the application of varying quantities of lime in rendering available to plants the nitrogen in soils to which nitrogenous fertilisers had also been applied. In these tests the results, when taken as a whole, were exceedingly uniform. It was found that whatever method was employed to test the ammonifying power in soils, applications of lime led to the gradual production of increasing amounts of ammonia, which is, of course, a readily available source of nitrogen. Likewise, the general conclusion in the nitrification tests was that applications of lime cause increasing nitrate production according to the amount of lime used, the gains being almost proportional to the amount of lime, up to three tons an acre. With reference to the accumulation of nitrates in soils, it was found that applications of lime led to their slight increase; and in tests of nitrogen fixation the application of three tons of lime in all cases seemed the most profitable from the standpoint of actual nitrogen fixed in the soils.

The denitrification experiments showed that there was a complete transformation of the nitrate nitrogen into protein, and that no loss had occurred as a result of testing the denitrifying power of the soil in solutions and in beakers. Similarly in the soils themselves, there was no loss of nitrates, just as much being present at the end as at the beginning of the experiment. "The reason for this lack of denitrification might be the absence of denitrifying bacteria, or it might be that the conditions of the experiment were not optimum."

To test the accuracy of the laboratory experiments a field test was made with oats as a crop, and the conclusions from this experiment are as follows:—Applications of lime up to three tons an acre increased the crop yield; half-ton and ton applications of lime caused a very small increase; the nitrogen content in the crops is increased much more rapidly than the yield itself; and the crops from the soils that receive small amounts of lime contain more nitrogen than those from the check soils, though the weights are virtually the same.

The practical lessons to be learned from these elaborate researches on liming are that the application of lime to soils in quantities ranging from half a ton to three tons an acre will render more available the plant foods in soils and fertilisers, thereby improving crop conditions; that an application of lime is practically equivalent to the direct use of the essential fertilisers of nitrogen, phosphoric acid, and potash, since lime forms soluble compounds of these plant foods and thereby increases crop yields; and that, when experience teaches the farmer that his soils need liming, he can confidently make use of lime up to three tons an acre without danger of injuring his land or lowering the yields of crops.

POULTRY NOTES.

BY D. F. LAURIE, Poultry Expert and Lecturer.

OPERATIONS FOR NOVEMBER.

THE GROWING STOCK.

It is presumed that all breeders have had a successful hatching season, and are now attending to the last hatchings. The later hatched chickens will need every attention if they are to mature and become fine, well-developed specimens. They must be allowed as much succulent green food as they will eat, and particular attention must be paid to the drinking water.

Shade must be provided, as the sun is at times very hot, and in a few weeks we may experience our usual heat waves. Frames, on which brushwood is placed, or on which calico, canvas, split wheat bags, &c., are stretched, will serve the purpose admirably. Many suburban breeders neglect to provide any shelter for their birds other than ramshackle structures which must be as hot as ovens. On hot days, where water is available, the ground under these shelters should be soaked with water. The birds will appreciate the cool, damp soil, and young stock will scratch therein and thrive accordingly.

Grading.—Separate the growing chicks and ducklings into various sizes. Do not keep large and small together, as the latter suffer. This is a very important, though generally overlooked, point.

Culling.—All weakly, deformed, and otherwise inferior specimens should be destroyed, as no good purpose is served by attempting to rear them. Weakly specimens, if they reach maturity, will breed weakly progeny.

Breeders of show stock may discard all badly mismarked stock and those which show palpable defects. It will take the average breeder all his time to do justice to his best chickens, &c.; why waste time and food on stock that will be of little, if any, value?

Separate the Sexes at an early age: This applies especially to Leghorns, Andalusians, Minorcas, and other light breeds. The little cockerels are often precocious, and, in addition to worrying the pullets, will fight among themselves, and thus much harm results. House the cockerels as far from the hens and pullets as you can; they will be more contented and will fight less. When reviewing a flock of pullets or a flock of cockerels it is easy to cull out the inferior birds and wasters. It is also a good plan to select the best and most forward and pen them apart. The cockerels should be carefully culled, as only a certain proportion, of even the best, will be ultimately retained.

PULLETS FOR LAYING COMPETITIONS.

Each year, when the time arrives for entering pens, or later on for forwarding them, it is reported that certain breeders are unable to do so because of some of the following reasons:—1. They have not enough pullets. 2. The pullets are too old and have been laying for some time. 3. The pullets are too young and will not lay for a month. 4. Neighbors' cats or dogs have committed serious depredations and the chicken yards are empty.

The Laying Competitions serve many purposes admirably. They allow breeders the opportunity of a rigid public test. They afford the public an opportunity of contrasting the merits of the strains of various breeders. They demonstrate the value of strain, of good housing, of scientific feeding, and of careful attention. They stimulate young breeders and invite the uninitiated to enter the ranks of breeders. They assist in the distribution of large quantities of eggs and large numbers of chickens and stock of high utility value among the producing community. They form one of the finest advertisements that the State can have. There are breeders in millions throughout the world, and the thousands of poultry journals have more or less to say about the South Australian competitions. Does the reader wish to compete, and thus add his help to the good work? If so, is he or she one of those who have the foregoing excuses to make? If so, the answer will be --

1. You must breed successive batches of pullets, and should have at least 20 from which to select your final pen. You will meet some of the best laying strains in Australia and perhaps the world, so any six pullets picked up haphazard will not have much chance of winning. Before it is too late you may perhaps buy some chickens. Of course, in the latter case the credit of breeding really belongs to the man whose stock bred the eggs or the chickens.

2. It is, of course, a poor policy to let your pullets lay 20 or 30 eggs each before you send them to the competition. Moreover, pullets when laying should not be sent on a journey.

3. If too young the chances are that they have, when at length they begin laying, lost too much time and have too much leeway to recover.

4. Secure yarding and housing will generally prevent the depredations of dogs and cats. At times it is necessary, however, to adopt more certain measures. A stitch in time saves nine.

Do not Force your Competition Pullets.—This is a common error and results in many complications. Feed well and keep the birds growing. Change them from run to run as often as you can. Change does them good, promotes growth and retards the precocious instinct to begin laying at an early date. The longer the period of maturity the better the frame will develop; also the organs of reproduction. Small eggs are generally laid by these precocious pullets. Give great variety of food, and if obtainable use a good proportion of oats. Use neither meat nor green bone. Give plenty of cut green food, and let it be fresh and sappy. Green food contains the valuable mineral

elements which are lacking in grain foods and seeds. The pullets may have exercise, which is best afforded by supplying plenty of short straw, in which the grain is scattered. Competitors are requested to carefully read the regulations. This is not always done.

POINTERS.

Look out for vermin, and take prompt steps to eradicate any discovered. Vermin-infested stock cannot be expected to thrive.

Use kerosine in the poultry houses, and flood cracks and crevices and apply liberally to the perches.

Nest boxes as usually seen are harbors of vermin. Make the nests on the ground and screen them with a piece of sheet iron. Use insect powder in the nests. Do not apply kerosine nor any strongly smelling substance.

Scrub out the drinking vessels and scald them at frequent and regular intervals. During warm weather just tinge the drinking water with a solution of permanganate of potash (sometimes called Condyl's crystals).

If short of green food, sow in prepared beds some rape or maize and water liberally. Sprouted grain is an excellent food used in strict moderation. When the sprouts are allowed to grow the green growth is excellent green feed.

Now the breeding season is over, all male birds should be shut up in yards by themselves. The breeding stock will then soon produce infertile eggs which are of good market quality.

Wash the shells of all eggs sent to market. Pack carefully, and use patent egg boxes provided with cardboard fillers. There are some in stock at the Produce Department, price 2s. 6d. complete; capacity, 25 doz. They will last a long time.

If your birds are not doing well write at once for information or advice. Do not wait until the birds are dead.

NOTES ON EGG-LAYING COMPETITIONS.

ROSEWORTHY AND KYBYBOLITE POULTRY STATIONS.

The appended reports of the Superintendents will prove interesting to competitors. We are now approaching the time when the seasonal forecasts will be indulged in. Although the leading pen at Roseworthy has about 100 eggs to the good, as compared with the leading pen (1911-12) on the same date, it remains to be seen whether the present leader will maintain much of the advantage gained. Last year the leading pen, which made the world's record, put in some surprisingly good work until the termination of the test. During the last month the winning pen made its best score; we may not witness a repetition. Given properly-bred birds, last year's test at Kybybolite has put to flight the unfounded opinions so often expressed, viz., that the locality is not suited to poultry. It appears as if this year's work will do more to show that such opinion was worthless. In cold wet districts the main consideration is adequate housing. Of course properly bred and scientifically-fed stock are a *sine qua non*.

ROSEWORTHY.

The Superintendent reports—The laying for the month has shown a steady all-round increase, and averages are being well sustained. The general appearance and health of the birds is good. The following deaths have occurred:—One in section 1, one in section 2, and one in section 3. The first was due through cannibalism, the second bird was a waster, and the third showed no outward signs for cause of death. The owners were informed of their losses, and two of them replaced their birds immediately; but the other competitor is carrying out his former policy of ignoring the incident, which is to his disadvantage only. Section 1 has supplied 20 broodies; section 2 has been content with 101; while section 3 has failed to produce any. The weather for the month has been of a mild nature; wind has prevailed on 26 days and has been of a moderate character, with two or three exceptions. The average maximum temperature was 71·5°, the average minimum 38·7°, with 86·2° and 27·3° as the highest and lowest readings. Rain fell on five days, registering a total of 94 points. Reviewing the birds, it is gratifying to note the tight-feathered appearance of the majority, which indicates a continuance for some time of the steady output of eggs. While nothing brilliant has been achieved by way of weekly individual scoring, a satisfactory fair all-round average has been maintained, thus indicating a grading-up process right through the course of breeding. This is more desirable in a competition than two or three brilliant pens and the rest nowhere. Comparing the averages for the present test with those of last year we find a general increase in the production of light breeds, with a small easing off with the heavy breeds for the same period of competition. For 1911-12 the average per pen for light breeds was 552·6; for the heavy section 523·6; while for this year the pen average for section 1 is 613·3; and for section 2 499·7; while for section 3, or scratching house test, 592·3. This latter test is an innovation at Roseworthy, and is being tried with a view to testing the productiveness of hens enclosed in a shed with the floor covered with litter against birds of the same strain allowed the open yard and house during the cold and wet period of the year. So far this test has shown the averages in favor of the open yard birds; but these results may not have been obtained entirely owing to the house conditions so much as to the fact that birds reared under free range conditions would naturally resent being shut up for a period of six months. These birds now have open yard conditions, and it will be interesting to note their efforts to make up the leeway during the remaining five months. The most noticeable feature about these birds is the development of comb compared with the birds which have had free range all the time. The pen average in this test with 134 pens competing is 583·9, against that of 546·8 for 126 pens last year.

Inter-State Competitors.—In the present test 29 pens are competing in section 1 in the interests of the other States, and to show that these birds are holding their own, I can quote a pen average of 619·1; section 2 contains 10 pens with an average of 485·3; and section 3 has two pens with an average of 525. In addition to the favorable figures put up by these birds, inter-State competitors will be pleased to learn that their birds are all enjoying good health and look well and compare more than favorably in size with the majority of South Australian entries. Although the latter are noted layers, one is faced with the fact that many of the birds are very small, and pens have been selected with an unevenness which is very noticeable. This may have been caused through circumstances over which competitors had no control, but it is nevertheless a difficulty which it would be well to overcome.

KYBYBOLITE.

During the month five birds in section 1 died, death in all cases being due to oviduct troubles. Two died in section 2; these were suffering from paralysis. Otherwise the birds have all been in a good healthy condition. The laying started to fall away a little towards the end of September and the beginning of October, consequently I let the birds out for the first time, and they are now given the run of the yards during the day time. The yards are all planted with kale, which is about 3ft. high, and in the hot weather will shade the birds and also provide a good supply of green feed. The leading pen, F. Lacey's, has eased up slightly, but the birds are all looking well, and I expect a good deal more from them before the year is out, as they are about 100 in advance of the leading pen for the same period last year. The second pen, owned by Moritz Bros., are looking well, and as the strain has been proved as layers before, there ought to be a good score put up by them and a fight for the leadership. Pen 22, "Herdsheld," are looking well and are putting up some good weekly scores, and possibly will be somewhere up at the finish. In section 2, Herdsheld are leading with a fairly good score, considering that they were practically two months doing nothing. In section 1 two birds had to be removed for broodiness, and eight in section 2. The weather has been all that could be desired during the latter part of the month, though earlier it was dull and windy. The mercury reached a maximum shade temperature of 80° and a minimum temperature of 33°.

D. F. LAURIE, Poultry Expert.

EGG-LAYING COMPETITIONS.

TWELVE MONTHS' TEST.

ROSEWORTHY.

[Started April 1st, 1912, and to terminate March 31st, 1913.]

D. F. LAURIE, Poultry Expert.

ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board of Agriculture was held on Wednesday, October 2nd, there being present Messrs. A. M. Dawkins (Chairman), G. R. Laffer, C. J. Valentine, C. E. Birks, G. F. Cleland, J. Miller, Col. Rowell, Professors Lowrie and Perkins, and G. G. Nicholls (Secretary).

ARTESIAN WATER.

A letter was received from the Engineer-in-Chief in answer to an inquiry which had been forwarded to him by the board, as follows:—"So far as South Australia is concerned there has been no apparent decrease in the flow of artesian bores, but this has, I understand, taken place both in New South Wales and Queensland, and may arise from a depletion of the water supply. At the recent Conference on artesian waters held in Sydney it was considered advisable that action should be taken to regulate the bores tapping the artesian supply with a view to its conservation. This matter, I believe, is still under consideration by the representatives of the various States at the Conference."

RESOLUTIONS FROM CONGRESS.

Compulsory Registration of Stallions.—This matter was held over till a future meeting to allow members time to fully consider the discussion and resolution from Congress.

Selling Fat Cattle by Live Weight.—It was decided to ascertain the views of the Pastoralists' Association respecting this proposal, as representing the largest suppliers of fat cattle, before taking further action.

Import Duty on Superphosphate.—With reference to the resolution protesting against the imposition of a duty on super., the Secretary mentioned that at the Conference of Ministers of Agriculture in Sydney some time ago it was decided that the matter should be dealt with at the forthcoming Premiers' Conference. The Board therefore decided to send the resolution, with which it agreed, on to the Minister.

Wheat over Weighbridge.—The desire of the Congress that the board should endeavor to secure the introduction of a system of weighing wheat by the load over weighbridges was tabled. The Chairman was satisfied that it would save time and a few pounds to the grower on the turn of the scales. The Secretary mentioned that in New South Wales the wheat-growers were keen to have weighbridges for the purpose of weighing their produce. The railway authorities in that State, however, declined to consider any request for a weighbridge unless the quantity of wheat dispatched

from that particular place totalled 10,000 or more bags annually. He had learned that in South Australia in 1910 there were 100 stations from which 10,000 or more bags were sent away. Professor Lowrie could not understand why the present method of weighing each bag singly was tolerated, although there had been justification for carefully weighing and sampling every bag. Ultimately Professor Lowrie seconded a motion by Mr. Cleland to consult the corn trade authorities of the Chamber of Commerce, which was duly carried.

HORSE STUD BOOK.

The Gawler River Branch wished to know whether any action had been taken in respect to the formation of a horse stud book. The Secretary indicated that the Farmers' Congress had discussed the matter last year, and a recommendation had been forwarded to the Minister asking that a report should be secured from Professor Lowrie. The Director informed the Board that he had not furnished a report for more reasons than one. He had been anxious to discover the extent of the interest in horse-breeding, and how his scheme for the improvement of stock would be received by those particularly concerned. Had that or something similar been adopted the need for a stud book could have been urged with greater force. Personally, he considered that the demand for a stud book should come from the breeders, and that they should be the controlling power. The book should be kept by the Royal Agricultural Society. He was prepared to report in favor of the breeders forming themselves into an organisation and approaching the society with the object indicated; but he would not recommend that the work should be undertaken by the Agricultural Department. Col. Rowell believed that the question had been brought under the notice of the Agricultural Society, but the expense involved had proved a stumbling block. He thought it would be a good plan for the Professor to meet the Council of the society and put the position before it. If the matter was left in his hands he would make the necessary arrangements. Professor Lowrie said he would gladly do so if it was the wish of the society. He considered that the adoption of a stud book would do more towards improving the stamp of horses than the compulsory registration of stallions.

DATES OF FRUIT AND VEGETABLE MARKET.

Mr. Miller drew attention to the fact that many gardeners were opposed to the Monday fruit and vegetable market, because of the Sunday work involved in getting produce ready. Col. Rowell and Mr. Laffer pointed out that the large demand for supplies for Broken Hill made it necessary to hold the market on the days now ruling. Mr. Laffer added that the growers could not afford to have any restrictions placed on the marketing of the

produce. There was much unnecessary Sunday work done, however, such as digging potatoes—a job that could very well be done during the week. He thought that those growers who observed the Sabbath did not lose much by so doing.

A NEW BRANCH.

The formation of a Branch of the Bureau at South Loxton was approved with the following gentlemen as members:—Messrs. A. Lowe, H. Lowe, C. Durdin, A. Durdin, C. Swinbourne, C. Webber, S. Lowe, J. Lowe, R. Beer, H. W. Russell, A. W. Russell, R. J. Russell, K. Kendall, W. B. Russell.

NEW MEMBERS.

The following gentlemen were approved as members of the Branches shown:—Elbow Hill—J. F. Brooks; Sutherlands—A. M. Twartz, J. Badge; Coomooroo—C. Phillis, C. Phillis, F. Gregory, L. Avery, A. Brice; Hartley—W. Cross, H. Cross, A. Wundersitz; Wepowie—G. Goss; Coorabie—R. R. Muegge, E. Oats, D. McLeod; Kingscote—B. H. Bell; Green Patch—H. Hill, C. Dorward, H. Schwerdt, T. Murray, A. Murray, D. Murray, S. Bailey; Coorabie—J. Jackson; Clarendon—H. A. Giles; Minlaton—J. Nankivell; Meningie—S. Yates, F. R. Deane; Crystal Brook—A. Story; Kanmantoo—T. B. Mills; Spalding—G. Page, D. Pryde, C. T. Cadzow, M. J. McCarthy, C. H. Wilson; Bute—L. Simon; Clare—J. J. Slattey, J. Burgess; Pinnaroo—H. J. Harfield; Green Patch—C. Venning; Friedrichswalde—T. Prior, R. Marlow, G. Grope, L. Johnson, J. Michalaney; Ironbank—N. H. Coates; Blyth—F. C. Williams, T. Williams, W. Reinke, jun., J. T. Harman, A. V. Heyemann, E. C. Deland; Georgetown—A. Smallacombe, J. Bond, B. G. Dowd; Wilkawatt—D. Horgan; Narrung—C. B. Powell; Hartley—C. Hutson; Coomooroo—A. Pitchers; Morphet Vale—F. W. Crittenden; Koppio—G. Miller, sen.; Wirrabara—E. Pitman; Coonalpyn—J. Turner, jun.

LIFE MEMBER.

Mr. J. Schuppan, of the Wilmington Branch, was made a life member of the Bureau at the previous meeting, but through an oversight his name was omitted from the last report.

APPLE—DUNN'S SEEDLING.

FRUIT.

Size—Medium to large, ranging from 3½ in. to 3 in. on young trees to 2½ in. by 2¼ in. as a fair sample from mature plants. *Shape*—Conical and regular, widest in transverse section. *Color of skin*—Pale greenish-yellow when growing, turning to bright golden-yellow when ripe, suffused with brownish-red on the exposed side, indistinct dots scattered all over, showing slightly paler in the yellow, and darker on the reddened surfaces. *Eye*—Open, with short slightly erect and twisted segments set in a regular, smooth, shallow cavity. *Stamens*—Marginal, tube long, narrow, funnel-shaped. *Stalk*—Stout, ½ in. to ¾ in. long, clubbed at end, inserted in a fairly even basin, the sides of which are lined with russet in dry districts, but in wet localities the cracking of this russeted skin induces rough cork-like formations, which often split and spoil the apple. *Flesh*—Clear, creamy-white color, of very firm texture. *Flavor*, moderately sweet, and first-rate when cooked. *Seed cells*—Obovate, axile, with large central cavity; season, from March until September.

TREE.

Habit—Erect, stiff, and vigorous, forming closely-set short spurs and stout laterals along the limbs, giving them a knotted appearance. The bark varies from a dull grey to reddish-brown color, sprinkled with a few scattered white dots between the nodes. The habit lends itself to the erect cordon-like formation being given its main leading limbs, which, after the first few seasons, may be permitted to run untopped, more particularly when grown in strong soils. It is not a consistent bearer, but sets a fair to good crop on

DUNN'S SEEDLING APPLE.

A. Vaughan, Gent. Photograph.

alternate seasons. *Climatic conditions*—The climatic conditions found most suitable are those of the dry and warm portions of this State north of Adelaide, where the annual rainfall is 20in. to 24in., and no rain of consequence falls after the fruits are one-quarter grown. In wetter localities the cracking of the fruit condemns it. It blooms with Jonathan and Cleopatra in early October, and is ready for shipment towards the end of March. *Origin*—The apple figured herein was raised by Mr. William Dunn, of Gordon Bank, near Houghton, in this State, about 60 years ago, and is said to be a seedling from Stone Pippin, which it resembles in some respects. An apple which is claimed to be identical with this one is grown in Victoria as Munroe's Favorite, and in New Zealand under the name of Ohinemuri. It is not badly affected by diseases, and is almost immune from the bitter pit defect.

VINEYARD AND WINE-CELLARS

THE WHEAT MARKET.

Contrary to general expectations, the war in the Balkans had very little effect on the London wheat market, and prices locally during the month showed but slight variation. Writing in regard to the situation on October 4th, before the outbreak of hostilities, *Beerbohm's* says:—"Even if war break out, which is still doubtful, it would not necessarily interfere materially with the supplies of grain, unless some of the big powers be drawn into the struggle later on. Freights in the Danube and Black Sea have advanced decidedly for prompt boats, owing to many Greek steamers being detained on the other side of Constantinople by Turkey. Imports into the United Kingdom were very large last week, being about 200,000 quarters above the estimated consumptive requirements. The estimated stocks at the principal U.K. ports on October 1st amounted to about 2,000,000 quarters, or only 50,000 quarters larger than on August 1st. As the imports in August and September, notwithstanding small deliveries of English wheat, have been 500,000 quarters above the consumptive requirements, it follows that stocks in second hands have increased by over 400,000 quarters, as there is no reason to believe that the consumption, compared with recent years, has materially increased. Shipments were again on a very liberal scale, and since the commencement of the season have amounted to 10,830,000 quarters, against 9,090,000 quarters last season. Whilst North America is expected to continue shipping largely for some time to come, especially now that the Canadian proportion will be steadily increasing, exports from Russia and the Danube may not be so large later on, as anticipated, as there has been no general buying for distant positions. There have been a fair number of steamers chartered from Kurrachee recently, and the exports from India promise to continue liberal for the time of year."

The following tabular statement, taken from the same authority, gives the world's visible wheat supply on October 1st, as compared with that on the same date in previous years:—

THE WORLD'S VISIBLE WHEAT SUPPLY ON OCTOBER 1st.				
	European. Qrs.	U.S./Canada. Qrs.	Total. Qrs.	Eng. Aver'ge Price.
1912	8,180,000	6,330,000	14,510,000	31/7
1911	9,140,000	8,835,000	17,975,000	32/6
1910	11,360,000	7,715,000	19,075,000	30/1

STEAMER FREIGHTS.—(October 3rd).—Steamers from South Australia to United Kingdom-Continent, full cargo rates, new crop, 40s. per ton (1s. 1d. per bush.). Parcels, Port Adelaide to London, Liverpool, or Continent, 17s. 6d. per ton (5½d. per bush.); Port Adelaide to Melbourne, 8s. per ton (2½d. per bush.); to Sydney, 10s. 6d. per ton (3½d. per bush.).

SAILER FREIGHTS.—From South Australia to United Kingdom-Continent (Dec.-Jan.), 37s. 6d. per ton (1s. 0½d. per bush.); to South Africa, new season, 28s. 9d. per ton (9½d. per bush.).

DAIRY AND FARM PRODUCE MARKETS.

The General Manager of the Produce Department reports on November 1st:—

BUTTER.

The supply of cream to hand this month has been exceptionally large, and the quality has been excellent. Owing to this, and the very careful grading, there has been a very great demand for butter, the ruling prices for the month being superfine, 1s. $\frac{1}{2}$ d. per pound; pure creamery, 11 $\frac{1}{2}$ d. per pound.

A. W. Sandford & Co., Limited, report on November 1st—

BUTTER.—The rainfall for 1912 to date is 3in. less than the average, and some parts of the State are feeling the effects of this decided shortage. On the whole, however, supplies of butter and cream increased considerably, and values maintained with a very slight easing. Best factory and creamery, fresh in prints, sold at from 11d. to 1s. $\frac{1}{2}$ d. per lb.; choice separators and dairies, 10d. to 11d.; store and collectors, 9 $\frac{1}{2}$ d. to 9 $\frac{3}{4}$ d.

EGGS.—Extensive buying orders on this market, together with local picklers putting away for future requirements, have caused values to hold up well. The market closed at 10d. per dozen for hen, and 10 $\frac{1}{2}$ d. for duck.

CHEESE.—Matured samples are scarce, but new make is coming along very freely. All the latter offering is readily cleared at 7d. to 7 $\frac{1}{2}$ d. per lb., while matured is selling at 10 $\frac{1}{2}$ d. to 11 $\frac{1}{2}$ d. per lb.

BACON AND HAMS.—Values have continued firm throughout the month, and the good prices here have attracted consignments from other States. Best factory cured sides realised from 10d. to 10 $\frac{3}{4}$ d. per lb.; hams, 1s. to 1s. 1d.

HONEY.—New season's take is now arriving, but the brisk demand is rapidly absorbing all lots at 3 $\frac{1}{2}$ d. per lb. for prime clear extracted; second grades dull at 1 $\frac{1}{2}$ d. to 2d.; beeswax, 1s. 3d.

ALMONDS.—The sale is somewhat slow, but the inquiry for kernels is good. Brandis are selling at 5 $\frac{1}{2}$ d. per lb.; mixed soft shells, 5d.; and kernels, 1s. 3d. per lb.

LIVE POULTRY.—Although increasing quantities were received, the supply was not nearly equal to demand, and buyers, therefore, bid keenly for all classes. Good table roosters realised 3s. 6d. to 4s. each; hens and cockerels, 2s. 6d. to 3s.; ducks, 3s. to 3s. 6d.; geese, 4s. 6d. to 5s. 6d.; pigeons, 9d.; turkeys, 10d. to 1s. 1d. per lb. live weight for fair to prime table sorts.

CARCASS MEAT.—The season for this line is practically over, the weather now being too risky to enable consignors to forward in safety. However, the consignments received, provided quality was right, met with a good market. Bright handy size shop porkers fetched 6 $\frac{1}{2}$ d. to 7d. per lb.; good baconers, 6d. to 6 $\frac{1}{2}$ d.; heavy and light sorts, 3d. to 4d.; nice dairy veal, 3d. to 3 $\frac{1}{2}$ d.; medium quality, 1 $\frac{1}{2}$ d. to 2d.

POTATOES AND ONIONS.—The month of October witnessed the culminating point in the shortage of potatoes, and prices reached their highest level. Gambier supplies are now exhausted, and new season's locals are beginning to make their impression on the market. Onions—On account of importations from abroad the price for onions has not advanced beyond last month's level. New season's onions are now being marketed. Present quotations—Potatoes, £15 10s. to £16 per ton on trucks, Adelaide or Port; onions, £16 to £22 per ton on trucks, Adelaide or Port.

RAINFALL TABLE.

The following table shows the rainfall for October, 1912, at the undermentioned stations, also the average total rainfall for the first ten months in the year, and the total for the ten months of 1912 and 1911 respectively:—

TO ADVERTISERS.

The "Journal of Agriculture" has a circulation of over 6,000 Copies monthly amongst the Cultivators of the Soil in South Australia, and consequently is a valuable medium for advertising Farm and Orchard Supplies and Requisites.

Particulars as to charges for space on application to the Department of Agriculture, Adelaide.

THE AGRICULTURAL BUREAU.

TWENTY-FOURTH ANNUAL CONGRESS.

(Continued from page 343.)

WEDNESDAY, SEPTEMBER 11.

The Congress was resumed at 10 a.m. on Wednesday, September 11th, there being a large attendance of delegates. The Chairman of the Advisory Board of Agriculture (Mr. A. M. Dawkins) presided.

SOME COMMON PARASITES OF LIVESTOCK.

Mr. F. E. Place, M.R.C.V.S., B.V. Sc. (Government Veterinary Lecturer), delivered the following address on "Some Common Parasites of Livestock":—

I venture to hope that the remarks I am about to make concerning some of the more common pests of the lower forms of animal life which affect our farm animals in South Australia may not be altogether without profit. My reasons for selecting this subject are twofold. First, because during my residence in this State I have noticed that common knowledge concerning them is not as accurate as it should be, and that in many cases a totally false impression concerning their importance exists—often those which cause a serious economic loss are ignored, while on the other hand those whose presence is really not very harmful are credited with being the harbingers of ills untold among stock, while many which do not affect stock at all are looked upon as scourges. This unsatisfactory condition of things is no doubt due to the fact that these small pests have been treated, like some subjects in the Bible, as things not to be mentioned in polite society; or owing, perhaps, to the unfortunate habit prevalent among scientists of bestowing most awe-inspiring names upon them, the man on the land has felt shy of having anything to do with them or their life history; whereas if they had been introduced to him as flies or worms he would have taken a keen interest in them, and by his observation added much useful knowledge to the somewhat scant information which we possess concerning many of them. My second reason is a personal one—that for many years I have found the study of the life history of these "little foxes" a fascinating hobby, not unmixed with practical utility, whereby I have been able from time to time to set forth the connection between these forms of life and the symptoms of diseases which have been thought to be of obscure origin; and therefore I feel that I may speak to you

about them with a little more confidence and self-assertion than would be justified were I to discourse upon matters less familiar. And in South Australia I have found one of the most charming fields for the investigation of worms that it has ever been my good fortune to alight upon, for truly here their name is legion. Although in the title of this address I have used the Greek form of their name, I have done so against my own inclination, and would far rather have spoken of them as flies and worms; but unfortunately these two good Anglo-Saxon words do not quite include some of the forms of life about which I shall want to say a little, and therefore for brevity's sake I have used the more comprehensive, if less comprehensible, term.

CLASSES OF PARASITES.

Parasites may be described as uninvited guests, and to facilitate description the methods of life which the host—the carrier of the lower form—and the uninvited guest live together are usually divided into three classes. First, when both benefit from the partnership, like the crocodile on the Nile and the little bird which picks its teeth, or the sheep and the starling. But with this form we have little to do. The second results in an advantage to one of the parties without harm to the other, a kind of Dives and Lazarus arrangement which need not occupy our attention. The third is the form in which we are more immediately interested, in which the residence of the uninvited guest is fraught with more or less unpleasant results for the host, and in these remarks I must confine myself to comparatively large guests, such as one can well see with the naked eye or by the help of a pocket lens. Time and the occasion do not permit of reference to those microscopic forms which require high magnifying powers and special methods of preparation for their demonstration.

We are dealing to-day with things that we can see and handle, and these we will for convenience again subdivide into three classes—

The first are lowly, one-celled bodies, whom individually we cannot recognise by the naked eye, but whose colonies we can readily see in the spotty livers of rabbits or the gullets of sheep. They have no common name; but, tiny as they are, rejoice in the lengthy titles of *Coccidia* and *Sarcosporidii*, which we may fairly turn into English as tiny dots and specks in the flesh. The former we find in the internal organs and the latter in the meat, and we will refer to them at a later stage.

The second are worms, which are numerous, and will require considerable attention. We shall divide them into flat worms and round worms, and subdivide them into numerous families.

The third are creatures with jointed legs, such as we commonly call insects; but for the moment I would discard this word for the more cumbersome description just given, because I must use it as a special name for groups which have in common bodies divided into three sections—head, chest,

and belly—which possess three pairs of legs, and often possess one or two pairs of wings; while the other branch of this third group have a head and chest combined and a belly, and upon their front section carry four pairs of legs. The insect class we may typify by a fly, and the four-legged class by a spider. To the latter belong all the mange and similar mites, with many larger ones, while the former will hold lice and fleas, and such small cattle.

The terms of tenancy of these guests are very varied; some live upon the outside of their hosts, some upon the inside; some spend their whole existence upon one host, others wander to different hosts, and in this way often act as the carriers of disease in a way I will touch upon more fully when speaking of some of the flies and fleas.

LIFE HISTORY.

In working out the details of their life history we find that we have many factors to consider. Time of year and character of the season often greatly modify their existence and numbers; some live in the air, like the bot fly; others pass part of their existence in the earth, like the blood worms; many are carried by water, such as round worms and flukes. The character of their eggs often has a marked influence upon their spread; those of the thin-shelled variety generally hatching out outside the animal body and invading their hosts in the early stage of their life outside the egg; while those in the thick-shelled sort are swallowed in their shells and hatch out inside their host, as in the case of the long, round worm of the horse; while others circulate in the blood stream, and finally rest in some selected spot in which to undergo development as in the case of the worm nodule in the bullock's brisket, which so upset the English press some few months ago. Some seek their resting place direct and settle down in it without further fuss, like the little pest which prefers the white parts of cattle for its home; while in yet other forms a special instinct seems to be at work, as in the warble maggot, fortunately unknown in Australia at present, which wanders from the bullock's gullet through its chest walls till it finally develops under the skin of the back.

To give you some idea how these pests multiply, I may mention that in eight weeks a louse may become the grandmother of 5,000, and in her lifetime the progenitor of 150 millions. One of the commoner blood worms often emits 30,000 eggs; figures which throw some light upon the enormous rate of increase which might and does occur if the conditions are favorable; but, thanks to a kindly Providence, as a rule the death rate generally keeps pace with the birth rate, else Commissioners of Crown Lands and Lands Settlements Boards would find their occupation gone. Yet the death rate has to fall off but very little to account for an enormous increase in these pests, which also can lie dormant for very considerable periods of time. A story runs that an attendant engaged in unrolling the mummy of an ancient Pharaoh contracted the itch from his majesty's wrappings; but whether this

be true or not, it is no uncommon thing for eggs of worms to lie dormant in the mud of dams and such congenial places for four years, while others can be frozen and unfrozen without interfering with their vitality.

Luckily, however, this tenacity and vigor is materially discounted by the vital forces of the host, and in most cases probably the invaders are digested as part of an ordinary ration, or their eggs poached by the rays of a South Australian sun. But it may be taken that as a rule young animals are less capable of resisting the attacks of these pests than mature stock, while the constitution of the host has a marked action on the development of the pests; though, on the other hand, if they begin to make headway, they impair the most vigorous constitution, and form surroundings more to their taste; while seasons have a decided influence for good or bad. And one should perhaps mention it with bated breath at a Congress of South Australian farmers, but much depends on the hygienic surroundings of the hosts; and can it be said that in the majority of cases in this State that the surroundings are hygienic? Are those heaps of soft, comfortable horse dung, stirred by rolling teams or wafted by gentle brickfielders, entirely devoid of eggs or worms? Are those dams whose edges have crumbled under the hoofbeat of many a head of stock, wholly innocent of the larvæ of blood and other worms? I fancy if the money that goes to buy worm powders were to purchase shovels and brooms, or were expended in water lifts and troughs, that in a few years' time there would be less heard of blood worms and their doings, there would be young stock with the bloom of health upon their coats instead of dejection and misery writ large upon their forms, and in the long run elbow grease and foresight would be found to be cheaper than santolin or tartar emetic; and I am quite sure that they would be more effective.

The farmer may say, "Oh yes, all this is very interesting to a man sitting in his laboratory, but what use is it to me who want to know how I can tell whether the horse has got lice or if his inside is rotten with blood worms?" It would be impossible in the scope of an address such as this to go into detail as regards the signs by which one can recognise these things, but in every case there is one infallible sign, namely, the presence of the pest itself. It is easy to know that the bot fly is about, though eight months later it may be difficult to tell how many of its larvæ are hanging on to the inside of the stomach of one's favorite colt. No one can err in declaring that a mare has worms when one finds one 8in. or 9in. long on the dung she has just passed; but it is not so easy to tell whether she is breeding thousands inside her as fine as thread and only half an inch long; and looking at a patch of dung in a hundred acre paddock will not help much; neither can lice be seen by a casual glance in at the stable door; but in all these cases a careful and systematic search will enable anyone to demonstrate the presence of the pests if there. Then if there is still a doubt, a little tinful of the dung, or a tobacco tinful of the scrapings and hair sent to the Chief Inspector of Stock direct

or through the Secretary of the Advisory Board, will enable the veterinary officers of the department to give a definite opinion. In rough outline, when pests are upon the skin there is itching, loss of hair or wool, and loss of condition; when they are inside the body there is loss of condition, bloodlessness, frequently diarrhoea, and failure to respond to good feeding. In certain cases where there are definite symptoms I will refer to them when dealing with the particular pest to which they are applicable.

NECESSARY PRECAUTIONS.

The manner in which these pests derive their sustenance varies with the character of the parasite. On the skin, for instance, some merely hide under the hair and feed on the waste of the skin, others burrow deeply into it. Many internal worms simply lie in the passages they prefer, and derive their living from the substances with which they are surrounded; others burrow into the tissues of the organ and use them for their home and provender. Many, both outside and inside, actually suck the blood, and though their individual efforts are small, in the aggregate they work considerable mischief.

Owing to the varied effects of the different kinds of pests, it is well to obtain expert opinion as to the sort with which one has to deal, and to learn the best ways of preventing their attack or of lessening the ill effects which may arise therefrom. But at the risk of repetition I would point out that the great preventive is cleanliness of the animal and its surroundings. Carelessness in the disposal of the eggs of these pests is at the bottom of nine-tenths of the mischief that they do in South Australia. The drinking up of thousands of tiny maggots stirred up in the mud of the edge of the dam, will certainly result in some at least finding a congenial home. The slap-dash use of the brush, first upon a lousy colt and then a clean one, will be an effectual way of carrying the mischief-makers over. The close cropping of the grass, near the roots of which are lying the immature flukes, will certainly result in the infection of the flock. The careless flinging of the paunch with its little watery cysts to the expectant sheep dogs will rebound in their becoming affected with tapeworms, which in turn will spread the disease a thousand-fold.

HABITAT.

But we have spent enough time on these generalities, and must proceed to deal with certain of the commoner pests in more detail, so that practical good may issue from this dissertation; and that this may be the more readily referred to, I propose to mention the districts of the body upon or in which the various kinds of pests may be most frequently found, and briefly touch upon their form and habits and the means to be taken to eradicate them or minimise their bad effects.

EXTERNAL PESTS.

Naturally one commences with the skin. Upon or in the substance of the skin of our farm animals one is again able to divide the parasites into three main groups. First come insects, either perfect or in larval stage, including fleas and lice. Then the spider family of ticks and mange mites, with one or two less familiar forms. Lastly, few in number, worms. And not belonging to the category of to-day's pests, low forms of plant life which produce ring-worm.

Among the flying insects we may take a glance at the gnats and flies, which buzz, suck blood, and come in swarms. Many of these prefer the evening for their wanderings, and seek their hosts in the open paddock. They annoy, and often carry disease upon their beaks; but under South Australian conditions little can be done to get rid of them beyond treating animals in work, which may carry leaves or rags or nets to frighten them off, and the c may be dressed with strong-smelling essential oils such as tar, turpentine, eucalyptus, or various disinfectants. Perhaps the most effectual way to keep them off is dense smoke. Next, we find a family of flies, fairly small, and not at all vicious in appearance, which buzz and prefer the shade of the stable; but they bite and raise little lumps which soon disappear. They are known as breeze flies, or *Tabanidae*, and in other countries work havoc by feeding on animals in whose blood are microscopic parasites, which are thus transferred to healthy hosts upon the sucker of the fly.

In South Australia the freedom of stock from this class of disease keeps the flies in a fairly harmless condition; but the tropical conditions upon our northern borders are very favorable to the introduction and spread of such disease, and should they come, the flies may carry them southwards; so, as prevention is better than cure, it is well to keep the breeding of these flies in check. The formalin method described in detail in a recent number of the *Agricultural Journal* is simple, cheap, and effective.

Students of Kipling and anti-suffragettes will rejoice to note that the mischief-workers are always the "female of their kind." A larger breed, like small bluebottles ("Stomoxys") and the stable fly, are less sociable and work singly, as a rule, and up to the present have not been found guilty of mischief in this State, though in Africa and Asia they are in the forefront of the ranks of dangerous disease carriers.

Next we come to a curious family of flies, one of which is wingless, and is commonly known as the sheep tick, but is not a tick at all, and will be noticed in more detail in a few moments. The other is the little squat fly which runs and tickles horses so, especially under the tail, finishing its attentions by a sharp bite, which not infrequently evokes a protest in the way of a kick, or a fling of the tail over the reins and a bolt. Next come the families of shining bodies and generally woolly legs, who themselves are only indirect authors of evil by laying their eggs in wounds and so forth, that their

maggots may find plenty of food for their voracious appetites when they hatch out. The presence of these flies in the summer makes it imperative to dress wounds such as result from injuries or castration with substances like tar, to keep off the pests. In this family we find the flies which work such havoc among sheep in the neighboring States—*Lucilia serricata*, of blue body, and relations of similar form. No doubt short docking favors the attention of these pests, and their relative infrequency in this State is probably due to the tails being left somewhat longer here. Though not habitually offal eaters, much preferring the living tissues, they do at a pinch survive on dead meat, which is the favorite breeding-ground of their cousins; and it is bad practice to leave fly-blown carcasses about, though it still continues to be done in spite of repeated warnings from Virgil downwards, for every fly developed means thousands more in a very short time. As preventive dressings, one may recommend arsenic dips and attention in the way of dagging. As treatment, I prefer strong solutions of corrosive sublimate.

The next family is that to which the bot fly belongs, and will be noticed in fuller detail directly. These flies are not blood-suckers.

Lastly there are the gad flies, so often confused with the bot flies, but which are blood-suckers, and whose bites cause serious annoyance to both cattle and horses.

The fleas are blood-suckers, and are not of much importance to us to-day, although at times sources of great annoyance to horses in their heels; our friend the dog has also to put up with a great deal of annoyance from them, and one form of tapeworm from which he suffers passes part of its life in the flea. They demand much keener attention from doctors, as they are implicated in the dissemination of plague.

The next family, the lice, are of much more practical interest, for different members of the family affect all our animals. They are insects without wings, and therefore remain for the most part upon the animal upon which they are bred, their transference being by contact with other animals, in which way emigration is very actively carried out; and in this State there is a danger of their becoming a very serious economic pest upon sheep if farmers neglect to loyally assist the Stock Department in the efforts of its officers to control their spread. Though I have no wish to pose as an alarmist, I can easily imagine them becoming as serious a menace to the wool industry as scab was formerly. Lice have sucker mouths, and live upon blood and waste thrown off from the skin. The horse harbors three kinds, one of which is rare in this State. The other two are, unfortunately, common; the larger is grey, and the smaller yellowish. Cattle are also the proud possessors of three sorts, the commonest being the one commonly found upon calves, which is a chestnut color. In both horses and cattle they are easily got rid of by oily dressings, which suffocate them, but must be repeated from time

to time as new families hatch out. Tobacco water is also very fatal to them.

The sheep louse, to which I referred a moment ago, rejoices in the name *Trichodectes sphærocephalus*, which is many times longer than himself, he, or rather she—for again the fair sex is the greater sinner—being about three-twenty-fifths of an inch in length. The color is whitish-grey; the head rusty color, and broad as compared with the body. Repeated dippings with, as the Chief Inspector of Stock points out, poisonous dips—especially arsenical—will soon eradicate the pests; and as a practical authority on dipping his reputation has travelled far beyond this State, his recommendations being adopted in the Indian Empire; so that I would earnestly recommend farmers to listen to his warnings and carry out his instructions. The symptoms have so recently been described, and unfortunately in many parts may be seen upon affected animals, that I need not dwell upon them here, merely mentioning that a lousy ram will quickly infect a flock. The old country plap of oily raddle or black, in addition to marking his ewes, will kill many lice upon the parts from which they are likely to spread.

The practical observation that lice are most frequently seen on Lincolns, Shropshires, and so forth, rather than on the Merino, has a great interest and practical bearing, for it points to the strength of the Merino yolk being inimical to the development of the lice, and provides a practical hint as to the extermination of the pest should it get out of bounds. The observation is corroborated by laboratory experiment.

It is convenient here to refer to the wingless fly I mentioned a little while ago, generally spoken of as the sheep tick. This is a much bigger object than the louse, being nearly one-fifth of an inch in length, and brown in color. Its eggs, which hatch out about once a week, can be seen like tiny apple pips on the ends of the wool points, which indicate the presence of the insect on the fleece. It succumbs more easily to dips than the louse, but the dip must be well worked into the wool.

The pig harbors the biggest of the louse family, and in bad cases they seem to be running out of his eyes and nose. The homely remedies of oil and vinegar will effectually end their career.

THE ACARINÆ.

We may here leave the insect family as a whole, reverting to them for a few minutes when we touch upon bots and similar grubs, and turn our attention to the eight-legged spider family, the *Acarinæ*, among which we shall find many of the greatest economic import, of which we may mention the tick which spreads Queensland redwater and the mite which causes sheep scab in other countries; not here, for which you have to thank the vigilant action of your Stock Department, against whose orders, I regret to find, there is sometimes a tendency to rebel, which surely should not be the case when those orders bear the names of Valentine, Needham, or your present Chief Inspector—men whose administrative ability, backed by their practical

experience, should surely merit your fullest confidence and most loyal co-operation.

The life cycle of these pests is generally this: The egg produces a six-legged larva, which moults into an intermediate nymph, which in turn becomes the perfect eight-legged creature, from the sexual union of which proceed the fertile eggs of the next generation.

THE TICKS.

The largest members of this family that we deal with are the ticks, and luckily they do not appear to be responsible for much harm in South Australia among farm stock, although they maintain their bad reputation among poultry. But in Queensland they act as the carriers of the microscopic organism which breaks up the blood cells and causes the ravages of Queensland tick fever. The way ticks bite is of interest as explaining how they manage to carry disease. They saw their way into the skin, and then hang on by spreading out the blades of the saw, as it were, and between these they eject an irritating fluid which contains the organisms and brings a flow of blood to the part. This explains the difficulty one has in removing the head of a tick from a dog or other animal, and why it causes such an irritating sore when not removed. The sexes unite on the animal, and the egg-bearing female drops to the ground when ready to lay. She produces hundreds of seed ticks in the course of 15 to 20 days, and then shrivels up and dies. The seed ticks climb up blades of grass and so forth, and attach themselves to the hair of passing animals, and so are carried to new pastures. Should a large animal not pass their way, they are not averse to hiring a bunny as a means of transport to more favored climes.

The male tick is smaller than his mate, and flat. As a rule the various moultings take place upon the same animal. Dipping with arsenical dips, followed where possible by oily dressings, is effectual in destroying ticks, and tick-infested country may be cleared of them if it can be kept free of stock for 18 months; but this is a big proposition in a land where rabbits and kangaroos and such small deer may form temporary homes for the ticks and carry them all over the country.

A much smaller member of the spider family is the teatree tick, which is only too well known in the South-East. Almost microscopic in dimensions, it seems endowed with unlimited powers of irritation, both for man and beast. The unendurable itching which it causes may be quickly relieved by applying naphtha in some form, a convenient way being to dissolve some of the so-called camphor balls in oil or methylated spirit.

MANGE MITES.

The mange mites follow the rule of three, and form three groups which may readily be differentiated under the microscope—the *Sarcoptes* being roundish,

with short legs, the last pair of which are hidden under the belly; the *Psoroptes* are oval, with thick legs, all visible, and lobes at the lower end of the belly; and the *Chorioptes* have oval bodies and long, thin legs. Most of these mange mites go through their life cycle in six to 10 days, and hatch out in 24 to 48 hours. A member of the first generation, leaving 10 females and five males, at the end of 15 days will, in the sixth generation at the end of 90 days, be responsible for a million females, and half that number of males, populating Australia with a vengeance. Their presence is indicated by intense itching and loss of hair, quickly followed by loss of condition.

In the horse the *Sarcoptes* quickly spread all over the body, and, running about, cause the animal unendurable uneasiness, and may easily be spread to his neighbors. The *Psoroptes* confine themselves chiefly to the mane and tail, producing the so-called sweet itch, with the loss of hair and thickening of the skin due to the irritation of their burrowings. The *Chorioptes* affect the hair of the heels, and produce a form of grease without over much irritation. Scab in sheep is due to a family of *Psoroptes*, while in many instances the so-called but mis-named "cuckoo scab" is the result of the presence of *Sarcoptes*.

All these mites love the sun and warmth, so that when treating them it is advisable to have the animal out in the sun some time before applying the dressing, so that they may have come out to the surface in larger numbers and be more easily attacked; and it is well to break up their homes with an alkaline solvent such as washing soda which, with soap lather, soon chokes and kills them, or leaves them helpless to escape from the more drastic dressings such as arsenic solutions or tobacco water; while naphtha or benzine and oil will quickly allay the irritation their presence may have caused.

The last members of these animal external pest families we shall notice carry the name of *Demodex*, and produce similar effects to the ones just noticed, and in the dog cause a most persistent form of mange. But the members of the family of most interest to us prefer the white parts of cattle, where they live and multiply without causing much uneasiness; but should they take a fancy to the horse, and settle on a blaze, for instance, he will show by his rubbing and the consequent loss of skin how irritating they may be.

The worms which invade the skin are either not frequent in South Australia, or I have not yet had the good fortune to encounter them. They need not occupy our attention to-day.

Before leaving the skin, one must just notice in passing the low plant forms—moulds—which produce various forms of ringworm, not common in horses, though more northerly one form at least occurs fairly frequently. Probably "seedy toe" is due to one of these low plants. When they occur in animals they are frequently transmissible to man, which is especially the case with the form so common in mice, as was noticed last year; and there is a possi-

bility that they may be able to modify their form of existence and grow inside the bowels and take part in a form of poisoning common in South Australia.

INTERNAL PESTS.

Enough has been said about those parasites which live on the outside of the animal, and we will now turn to those whose residence is within, and therefore about which there is less accurate knowledge and a tendency to romance, founded on lack of facts.

Living in the digestive organs we find the one-celled *Coccidia*, tape worms of many kinds, two sorts of flukes, and numerous families of round worms, which may be grouped round types like the big round worm, the whip worm, the thread worms, the palisade or blood worms, the nodule formers, and one which, in the rat and pig, finds its home in the flesh. The tape worms of some animals spend the early days of their existence as watery bladders or cysts in others.

Following the regional plan, we will glance first at the mouth, at the back of which it is not uncommon to find leeches hanging on to the softer parts of the throat, and causing considerable disturbance. Salt dislodges them ; but when they are numerous or troublesome the horse should drink through a bag, as recommended by an old Arab horse doctor nearly 500 years ago. In the gullet of cattle and sheep one often sees the little white specks which are the fortified walls of the castles of a tiny worm, or the remains of a colony of one-celled animalcules. Passing to the stomach of the horse one very often finds in it tumors varying from the size of a pea to that of an egg, which are caused by a thread worm closely related to the one found in the beef nodules.

BOT FLIES.

One also finds bots, the larvæ of a fly which does not suck blood or bite or sting, but which glues its eggs upon the hair of the chin or legs most often, whence in a few days the grublets emerge to find their way into the stomach and develop into the well-known grubs called bots, whose history I have repeated so often quite lately that I may well be excused from reiterating it to-day. But a few moments may be devoted to the description of the most common of the bot flies, *Gastrophilus equi*, a medium-sized fly with a woolly, beelike body and fawn-colored bands, with rusty-colored feelers, often mistaken for its sting, an organ it does not possess ; its breast is blackish-red with black bands, its belly yellowish-brown with black spots, and the wings striped with a smoky vein and edges ; the hinder end of the male is blunt, but of the female pointed, curled under her and provided with two long projections, also often mistaken for a sting, which are used in the delivery of the eggs and their attachment to the hairs. It is no uncommon thing to find 250 to 1,000 bots attached to a stomach.

There are in this State at least three different kinds of bot fly, one of which prefers to lay its eggs so that they can develop in the lower bowel, and another whose larvæ prefer the small bowel to the stomach, and are not averse to sojourning in the gullet either.

Prevention and treatment have been so fully laid before the public upon quite recent occasions, and are available in the *Journal*, so need not occupy our time to-day.

In cattle and sheep we do not find bots in the stomachs, but frequently thousands of tiny thread-like worms belonging to several families, which often riddle the lining of the stomachs right through and cause very severe diarrhœa and serious changes in the blood. They are responsible for numberless deaths, especially among calves and lambs. Both the worms and their eggs are voided, and thus pastures become infected. Overstocking is a certain means of inducing a very serious outbreak. Of all the drugs which have been recommended from time to time, arsenic is the most likely to do good, and when a flock is affected every lamb should have one or two grains daily for a fortnight. A rough and ready way of dispensing and giving this is to dissolve a pound packet of Cooper's dip in 2galls. of hot water, and give from a dessertspoonful to a tablespoonful to each lamb, according to age, every morning. As damp favors the development of the worms in every way, removal to dry pasture is essential.

Passing on to the bowels, we find a great variety of worms capable of living in them; in fact, it is in this tract that we find the majority of worms, flat, round, or threadlike. There are three kinds of tape worm found in the horse, generally in the first portion of the large bowel. They differ from one's ordinary notion of a tape worm in so much as they are rarely more than 2in. long, and broad for their length, with a curious little round head; they are often mistaken for flukes, which, indeed, they somewhat resemble; but they are yellowish-white instead of brown, and on close inspection will be found to consist of transverse segments, as do all tape worms.

In the small bowels we find the common large, round worm, technically described as the bigheaded variety; but in practice one has to look carefully to find which is head and which tail. They vary in length from 8in. to 16in., and lie in the bowel tube, gaining their living from the juices which flow past them, and as a rule do not do much harm, unless they are present in large numbers, when they cause a chronic catarrh of the bowel, with diarrhœa, and symptoms something like those of lockjaw. As many as 1,200, aggregating 7lbs. weight, have been taken from a horse. Tartar emetic and aloes generally dislodge them, but they should be burnt and not left lying about, as their eggs are very tenacious of life, and find a dung heap an excellent incubating place. Large doses of arsenic repeated daily for 10 to 14 days are also good, and ordinary bluestone is often found to be very effective.

Near the lower end of the bowel we find the whip worms, so called because their upper part may be compared to the handle of a stockwhip, and their fine tail to the lash. They vary in size from $\frac{3}{4}$ in. to $1\frac{1}{2}$ in., and are yellowish-white. They do not do much harm, and are fairly easily dislodged, either by purging with aloes or by the use of enemas; in the latter case, 1oz. to 2ozs. of turpentine in a couple of quarts of warm milk is a very effective means of disturbing them.

BLOOD WORMS.

We next come to the so-called blood worms, the hard-mouthed ones as their scientific name indicates, of which there are several varieties, three being found much more frequently than the others. They are sometimes called palisade worms from their stiff, rodlike appearance. In addition to their family name of hardmouth they bear individual names, the largest being called the horse worm, or armed worm, the smaller bearing the name of a worm with four boring points, and the third the toothless one. They are all greyish-white in color, a fact that has misled many people, who have expected to see red ones. They do show red when they have just had a meal of blood, owing to their thin skins; but the little scarlet wrigglers one finds in water are no relation at all to them. The large ones are 1 in. to 2 in. long, and as thick as a grass stem; the others are shorter and thinner. Owing to an inadequate knowledge of their life history, they have been blamed on the one hand with causing untold mischief in the horse's inside, and, on the other hand, they have been said not to do any harm at all; as a matter of fact the truth, as usual, lies midway.

They are a very serious menace to the life of young horses, and less so to mature animals, though in no case can they be considered desirable guests, though it is by no means easy to get rid of them. Their life history is a vicious circle, and in briefly looking at it we will start from the point when the adult worms are ready to lay their eggs as they lie with their circular-saw-like heads firmly imbedded in the coats of the bowel. These thin-shelled eggs hatch out tiny microscopic worms either in the body or in mud, and these gain easy access to the blood stream either through being swallowed or born in the lining of the bowel; they go round with the blood stream till they find a suitable resting place in the arteries of the belly, especially one which supplies the big water gut with fresh blood, and here they stay and develop, using their circular saw to cut their way out when they want a change of residence; and it is while they are in the blood stream that they do the mischief, altering the character of that vital fluid, and thereby robbing the organs of their necessary nourishment, and even probably changing it from a life-bringing to a poison-bearing stream. But if in the animal's youth they have not been sufficiently numerous or active to cause acute mischief, the system grows tolerant of their presence and inured to the poisons

that they form ; hence it is no uncommon thing to find them in large numbers in horses which have evidently died from causes not in any way connected with the worms. Drugs such as tartar emetic and santonin have a deterrent effect upon their development, but are calculated to cause more harm to the animal which gets them than to the worms, especially if the animal is young. But while in India a blood disease of another nature was being treated, it was observed that the large doses of arsenic necessary in that case, and which could be well borne by the horse, were more than these worms could stand, and that although the adults might not be killed off, their broods most certainly were, and I feel certain that in recommending this drug to you, you will get better results than you have in the past. But prevention is better than cure, especially when the latter is by no means certain.

The dam-side is responsible for by far the greater number of blood worms found in South Australia, while the dung-bed of the stable probably furnishes the rest ; and it does not require a filter to be germ proof to stop them from getting into the water trough ; and a man's wages for a year cleaning the stables and yard will amount to less than the price of half a dozen valuable colts. While, too, it must be remembered that the hundreds of worms found in the blood vessels, bowels, muscles, and even kidneys of a horse are the potential progenitors of millions more.

Cattle and sheep harbor tape worms such as we generally understand them. Sheep have 12 varieties, of which two are extremely common in this State. Calves also are infested with a long, round worm, which is sometimes present in great numbers, and when such is the case it not unfrequently happens that the flesh is tainted with an unpleasant stink, although the worms are found only in the bowels.

The pig has large, round worms and several kinds of thread worms, which latter are suspected of aiding in the spread of swine fever. This animal is also infested with a peculiar form of round worm, which buries its head deeply in the coating of the bowel and spoils them for sausage skins.

The pig is also infested with a minute microscopic worm, which develops in the flesh and causes the animal great pain ; but worse than that, this *Trichina*, if eaten uncooked by man develops also in his muscles, and causes very serious disease. Fortunately in this State consumption of raw pork and other products of the pig is not common, so that the risk of human infection is small.

A useful remedy for ridding pigs of intestinal worms is $\frac{1}{4}$ oz. of powdered castor oil seeds given in a little milk and pollard ; care, however, should be taken to use only seeds deprived of their outer coat, for this is very irritating, and likely to set up inflammation of the bowels.

This is a convenient moment to glance briefly at a somewhat interesting phase of the life of certain tape worms which mature principally in the dog, but which spend the earlier part of their life in another host. This phase is

recognised by butchers, who speak of water blobs or water bladders upon the apron or caul fat or upon the skirt. These little water bladders are the early life stage of a common tape worm of the dog, while the similar watery blobs noticed upon the insides of rabbits represent a similar stage of another tape worm. Still another is found in the brain of sheep, producing "gid," with the curious stamping trot or constant turning in a circle. This again has its counterpart in the brain of the rabbit. The watery bladders commonly known as hydatids are the early life stage of a small tape worm of the dog, and unfortunately occur frequently in man as well as other animals. These cysts, as they are called, are the cause of serious disease, and care should be taken never to allow dogs to get at raw paunches and similar offal; and as dingoes and foxes are as much hosts of these worms as dogs, carcasses of animals containing these cysts should not be left about for them to get at. It is much safer to burn them, as when they have developed in the dog, and he voids them, each little maggot-like segment may produce hundreds of eggs, so that a district may soon become badly infested and serious loss of stock occur. Passing from the bowels to the liver, we frequently find it invaded by these cysts; sometimes nearly the whole of the liver substance is destroyed by them. In lamb's livers the cysts are very often small, and may be easily overlooked; but an inspection of the notch at the lower edge of the liver will often show it to contain a cyst, and in such case if the liver be cut into more will be found.

THE FLUKE.

The tiny *Coccidia* frequently attack the liver of animals and man, so that white specks in the liver should lead one to treat it as most probably dangerous for food.

The liver, especially of sheep, is the home of that interesting worm, the fluke, in shape and color like a half-penny. Its nature and life history are quite different to anything we have yet considered. Its eggs pass with the bile into the bowels, a mature fluke being the producer of 20,000 to 30,000, which pass out in the dung and hatch out in water, where at ordinary temperatures the young spends a short existence as free-swimming water animal-cule, which, coming in contact with a small water snail, burrows into its air chamber, and there changes into a bag full of living organisms, which develop into a higher form that leaves the snail and again spends an existence swimming about in water, and eventually sticks to the underside of the lower blades of grass, where it can be seen as a tiny white slimy speck, ready to be swallowed by the close-cropping sheep. And here it is of interest to notice that sheep with deformed mouths, which cannot crop close, escape becoming flukey.

The symptoms of fluke are too well known to need a description here, but it may be well to point out the four stages of flukiness. First, getting

the flukes by close cropping, especially on overstocked pastures which are wet. Second, the loss of blood and paleness. During the early stage of this period sheep may seem to fatten more quickly. Third, the rapid wasting and weakness. Fourth, the passing of flukes and eggs. Hitherto treatment has been most unsatisfactory, but during the last two years experiments have proved that the administration of extract of male fern will kill the flukes, and it is worth a trial in our South-East districts. Time forbids my going into detail of treatment here, but I shall be pleased to furnish it to those who wish.

Although I have claimed your attention for an inordinate time, I must ask you to bear with me a few minutes longer while we shortly pass in review that important class, the lung worms, just mentioning, in passing, that many of the boring worms and some of a wandering disposition may be found free in the lining of the chest and belly, and one kind finds a home in the glands of the caul fat, where the disturbances they set up result in diseases of the "dry bible" kind.

Leaving the digestive tract we turn to the breathing organs the nose, windpipe with its branches, and the lungs—for here we find the trouble popularly spoken of as lung worms; but as these will need a little more detailed description we will first glance at others which dwell in these parts. We find the *Coccidia*, to which we have referred before, and, similar in appearance, but of a vegetable nature, spores of various moulds often accompanied by the pollen grains of plants. All these go deeply into the substance of the lung and set up little abscesses.

The bot maggot of the sheep prefers the nose and the hollows of the bones of the face for its home. Popularly known as "grub in the head," it is a source of great annoyance to the sheep, which constantly stop, rub their noses with their front feet very vigorously, burying them in the earth and burrowing along in their endeavors to dislodge the offenders. This condition is sometimes confused with the cysts in the brain which cause gid; this, however, is totally different.

Occasionally wandering flukes will be found in the lungs; they are probably adventurers seeking new south poles, or out prospecting. Hydatid cysts are very common in the lungs, and during life produce symptoms which may be mistaken for tuberculosis or pleuro-pneumonia; but when an animal can be got at in the bails, a practised ear can detect the difference in the sounds of the chest.

LUNG WORMS.

Coming to the real lung worms, which are thread worms, we find there are at least eight varieties in this State, of which three are very common. Two prefer to live in the pipes of the lungs, and the third would sooner nest in the air chambers themselves, thus setting up inflammation in the lungs; and when the system is strong enough to wall them in with a limestone prison

cell, the little nodules so produced are sometimes mistaken for tuberculosis. Sheep suffering from lung worms have them in their systems many weeks before the symptoms are well marked, namely, the troublesome coughing fits, the discharge from the nose, paleness, loss of condition, and dry wool. The worms are actively breeding for two to four months of the year. Some varieties, of which one is the shorter chestnut-colored one, produce eggs; the others produce both eggs and living young. The eggs are very tenacious of life, and have been seen to hatch out after being thoroughly dried for more than a year; so it can easily be understood how pastures remain infected, ready to spread the disease, as soon as ever the weather is moist enough; and the heavy dews upon the hills supply this just as well as the low-lying swamps, as outbreaks on the Adelaide hills clearly show. Here again the danger of over-stocking and close feeding is evident.

As regards treatment, I prefer arsenic, as suggested in the case of blood worms, for this drug circulates rapidly in the blood and comes into direct contact with the immature worms in the lungs, killing them and weakening the adults, so that they are more easily got rid of. Personally I have never had better results from injections into the windpipe than from fumigation of the sheep, which latter is much more easily carried out on a large scale, and with fumes of cyllin or similar coal tar products is much safer.

Practically the remarks relating to sheep apply also to calves. The worm which most commonly affects the latter lives in the pipes, and produces both eggs and young.

Lung worm in the horse is much more rare than in other animals, but it is by no means uncommon.

The pig is very frequently affected with a variety peculiar to that animal, and the nodules formed by the walling-in of the worms is a very common sight in the slaughter-house.

There are still many parasites which I have not touched upon, such as those causing the nodules in beef in cattle coming down from the North, the so-called measles in beef and pork, which are the early stages of varieties of tape worm in man, and so on.

CONCLUSION.

I trust the sketches I have given of the careers of the more common ones will induce younger members of the Bureaux to take an interest in the wonders of their development, and in the inter-relationship between many of them and forms of disease whose origin is still obscure; while I hope I may have aroused among the older members an appreciation of the necessity of cleanly surroundings for stock, and the imminent risk of heavy loss they run by neglecting the destruction of such small things as worms and flies.

It is another application of the story of the loss of the shoemaking which brought about the destruction of the city; of the wisdom of the preacher who said, "Take us the *little* foxes that destroy."

Recent researches have demonstrated that mosquitoes brought about the downfall of the mighty empire of Babylon, by harboring the germs of malaria that sapped the vitality of the nation. The Panama Canal, which will mean so much to Australia, could never have been cut if the life history of a gnat had not been studied and worked out.

REPLIES TO QUESTIONS.

In reply to questions, Mr. Place said that turpentine mixed with linseed oil or milk was excellent for worm troubles of any sort. Care should be taken, however, to see that it was thoroughly well mixed, and for this reason it was well when administering not to keep the vessel holding it still. He would thoroughly recommend the oiling of horses suffering from ticks. The oil would suffocate the ticks. Stockholm tar was an antiseptic dressing for wounds. It was one of the best dressings they could apply.

IDENTIFICATION OF PLANTS AND WEEDS.

Mr. J. M. Black gave an interesting description of various plants and weeds which had been sent by Branches for identification.

He stated that the following plants had been received from the Branches mentioned :—

MORCHARD. —(1) Darnel (*Lolium temulentum*), a grass which has a bad reputation, but which is only dangerous to stock if it becomes infested with ergot or other fungi. (2) The winter-flowering form of *Blennodia cardaminoides*, a small native, belonging to the family of the *Cruciferae*, and which turns its seed vessels down into the ground in the same manner as subterranean clover.

CLARENDON.—Fumitory (*Fumaria officinalis*), a weak, straggling plant of European origin, often called "Pinkie" in our southern districts, from the color of its small flowers.

BLYTH.—Dense-flowered fumitory (*Fumaria officinalis*, var. *densiflora*).

KINGSTON.—(1) *Anguillaria dioica*, a small bulbous plant of the lily family, known as "Bull's Eye" in some parts of South Australia. The accompanying letter says—"It is thought to be the cause of the death of many sheep, and it also makes them lose their wool when it does not cause death." I cannot find any previous record against this plant. (2) *Vittadinia australis*, a small strong-scented perennial of the composite family. "Made its appearance at Reedy Creek some years ago and is now spread over most of the dry land in the district." Both plants are native.

LYNDOCH.—*Ehrharta longiflora*, a South African grass which has been long domiciled in South Australia. A good fodder grass in moist situations.

WIRABARA.—A luxuriant specimen of nettle-leaved goosefoot (*Chenopodium murale*), a European weed which animals generally refuse to eat on account of its strong odor.

HAMMOND AND OTHER NORTHERN BUREAUX.—Salvation Jane, snake weed, or blue weed (*Echium plantagineum*), a Mediterranean weed which has spread rapidly over the State.

MOUNT REMARKABLE.—(1) Brown's dock (*Rumex Brownii*). (2) *Darvesia genistifolia*, a prickly native shrub with pea-shaped flowers. (2 and 3) *Erodium Botrys* and *E. cicutarium*, two species of "Wild Geranium," both introduced. (4) *Bulbine bulbosa*, a yellow-flowered native plant of the lily family, sometimes called "Wild Leek," and alleged to be poisonous; but Prof. Ewart states that the poisonous effect appears to be the result of a scouring action on animals. (5) *Plantago varia*, the native plantain or ribwort. (6) *Geranium pilosum*, the native geranium.

MOONTA.—Wild onion (*Asphodelus fistulosus*), a bulbous Mediterranean plant, proclaimed as a noxious weed. Does not appear to be poisonous, but does much harm in pastures and elsewhere, and can only be eradicated by deep cultivation.

STURT.—Spurred vetch (*Vicia calcarata*), a blue-flowered leguminous plant from North Africa, often found here in sandy soil. Of some use as fodder, but may become a weed in cultivation.

PINNAROO.—(1) *Stipa elegantissima*, a species of spear grass with beautiful feathery awns to the seeds. When young, the spear grasses afford good pasture; but when the awned seeds are ripe they are apt to be a nuisance to sheep and lambs. (2) *Bassia diacantha*, so called from the two short spines on the seed capsule. A form of saltbush or cotton-bush. (3) Narrow-leaved cress (*Lepidium ruderalis*), a cosmopolitan weed with small notched seed-pods, often found in crops and growing nearly as tall as the wheat. (3) Common vetch (*Vicia sativa*), an introduction from Europe, useful as fodder, but often troublesome in crops. (4) *Rhagodia spinescens*. The prostrate and spineless form of this little native plant. Has small red berries and belongs to the goosefoot family. It is probably quite harmless. (5) *Senecio lautus*, a yellow-flowered native groundsel. (6) *Senecio magnificus*, another species with larger and very showy yellow flowers. (6) *Gyrostemon cyclothea*, an ill-scented native shrub of the phytolacca family of no known value. (7) *Olearia rudis*, a native plant with a blue flower resembling a Michaelmas daisy, and probably protected from animals by its strong scent.

KINGSCOTE.—(1) Petty spurge (*Euphorbia Peplus*), a European weed, not poisonous, but of no use. (2) Probably *Rapistrum rugosum* (Giant Mustard or Turnip Weed), found growing amid Berseem clover, but too young for certain identification.

COORABIE, WEST COAST.—(1) *Eremophila subfloccosa*, a shrub hitherto supposed to belong to West Australia only. (2) *Rhagodia Billardieri*. (3) *Templetonia retusa*. (4) *Myoporum tuberculatum*. (5) Native tobacco. (*Nicotiana suaveolens*). All Australian plants of no known economic value. Native tobacco is slightly poisonous.

Mr. E. Davies, of Urania, Y.P., had sent a specimen of *Pimelea curviflora*, a small native shrub, stating that he believed horses and sheep had died from eating it. Several species of *Pimelea* have been accused of harboring poisonous properties, but this has never been proved.

Onopordon acaule (stemless Onopordon), which has been proclaimed as a noxious weed under the mistaken name of *Cirsium acaule* (stemless horse thistle), was forwarded by another Branch Bureau. A very prickly thistle, with downy-white leaves spreading on the ground, which has become a nuisance on the plains near Adelaide in many places and over a wide stretch of country near the Murray.

Several other specimens had been forwarded by other Bureaux in too immature a condition for identification.

Proceeding, Mr. Black said—When plants are forwarded to the Department of Agriculture, the questions most frequently asked are “Is this plant poisonous?” or “Is it good feed?” Both are often very difficult to answer. Take two very common weeds with a bad name, one South African, the other Australian—the Cape tulip and *Euphorbia Drummondii*. In 1908 Mr. J. F. McEachran, at that time Veterinary Inspector of Cattle, collected a lot of the two-leaved Cape tulip (*Homeria miniata*), which grows so thickly in parts of the Adelaide park lands, and tried its effects on some cattle. Two calves refused to eat the weed. An aged cow in poor condition died with symptoms of paralysis after being fed for three days principally on Cape tulip. The fourth animal experimented on was an old, dry cow, which at first developed symptoms of diarrhoea, but afterwards ate the weed in large quantities without any ill effects. Yet Cape tulip, especially the one-leaved species (*Homeria collina*), has long had a bad name in South Africa as poisonous to stock, especially to travelling bullocks, which are turned out hungry at the camping places and do not know the weed. It may possibly be that there is really no poison, properly so-called, in the Cape tulip, but that the deaths which have occurred here and in other countries are due to animals gorging themselves on the indigestible leaves and stems.

Something of this sort is believed to occur in cases where healthy young cattle are suddenly found dead in summer paddocks where the only green plant to be seen is *Euphorbia Drummondii*. Careful experiments were made with this little native plant in New South Wales as long ago as 1886. Fifty-six pounds of the weed were consumed by six sheep in six days without the slightest evidence of bad effects. Mr. Stanley, the Chief Veterinary Inspector, who conducted the experiments, calls it a “wholesome and nutritious herb.” He allows, however, that the plant, when eaten greedily by hungry animals, may cause fatal indigestion, in the same way as might occur after a surfeit of lucerne or wheat.

A few introduced plants, such as the apple of Sodom (*Solanum sodomæum*), the tobacco tree (*Nicotiana glauca*), and the thorn apple (*Datura stramonium*),

are really poisonous—that is to say, they exercise an internal chemical action which produces serious or fatal effects; but most of our alleged poison plants are probably dangerous by the acute indigestion which they cause in animals who have gorged themselves on the first green feed which came to hand.

Coming to the next question so often asked, as to whether a certain grass or other herb is good for grazing or for fodder, I would like to suggest that on this point the farmer can instruct the botanist rather than the botanist instruct the farmer. The man on the land has the opportunity of making a hundred useful observations on this subject, observations which cannot be made in towns or in gardens. It is not to be expected that there will be entire unanimity of opinion. I remember that, in 1909, a member of the Tatiara Bureau forwarded to the department specimens of the woolly star thistle (*Kentrophyllum lanatum*) with the statement that he had found it first-class feed for stock, especially sheep. Now I should have thought that nothing short of a camel or a donkey could derive any satisfaction from eating this fearfully prickly plant, and I presume it is only when young that it can be eaten at all. If members of the Branch Bureaux would collect and put on paper their personal experiences as to the effect of both native and introduced plants on animals which eat them, and on the preference shown for certain plants, they would be doing an excellent work, and assembling a store of knowledge which could afterwards be consolidated and published as a whole. Where there is any doubt as to the identity of the plants on which observations are made, flowering specimens should be sent to the Department of Agriculture for identification.

A USEFUL GRASS.

I would like to draw attention to a grass which appears very promising in many of our districts, and of which several farmers have spoken well in the Pinnaroo district and the South-East. This is the many-flowered millet grass (*Oryzopsis miliacea*), a perennial Mediterranean grass, which also propagates itself very rapidly by seed. The *Oryzopsis* grows in very dry country in the Mediterranean region, and I think it well worth a trial in most parts of South Australia. I would also like to warn farmers against an insidious weed which has appeared in South Australia during the past five or six years, and which is spreading rapidly. Its English name is Lesser Bindweed (*Convolvulus arvensis*), and it bears much resemblance to some forms of our native *Convolvulus erubescens*. Both have the same pretty pink funnel-shaped flowers, but the European weed is aggressive, and when it once enters cultivated ground is very difficult to get rid of.

NOXIOUS WEEDS.

The Chairman--A resolution has been sent to the Advisory Board asking that an expression of opinion from this Congress should be taken as to whether the tobacco tree should be proclaimed a noxious weed.

A vote was taken on the question, with the result that Congress declared in favor of having it so proclaimed. By a further vote Congress affirmed that horehound should not be proclaimed a noxious weed.

Mr. H. H. Davie (Mount Remarkable) moved--"That this Congress is of opinion that the present administration of the Noxious Weeds Act is quite ineffective, and that the Government be asked to legislate with a view to taking over the administration of the Act and administering it by officers not resident locally." The reason for the resolution was evident to many. His Branch, in bringing the question forward, had no desire to in any way reflect on the district councils, but they felt that the matter was an exceedingly difficult one for the councils to deal with. In some cases some of the most important members of district councils were the greatest sinners as regards the non-destruction of noxious weeds. The clerks of the councils were the administrative officers, and it could well be imagined that if an influential member of a council received a notice to destroy the weeds he might make it very unpleasant for the officer concerned.

Mr. T. L. Truman (Tatiara) seconded the resolution. His Branch had found the Act unworkable.

Mr. McCallum (Willowie) opposed the motion. The Government were the greatest sinners. In places land belonging to the Government was covered with noxious weeds. Star thistle was the worst pest in his district, and the district council had spent a great deal of money in trying to eradicate it. Some of the land was so overrun with the star thistle that he did not think it would ever be eradicated.

Mr. Nicholls said that the Advisory Board had appointed a sub-committee to inquire into the question of the destruction of noxious weeds. Professor Perkins had gone through all the Acts dealing with the question, and as a result the Advisory Board had come to the conclusion that there was ample power given to compel the destruction of noxious weeds, provided action was taken under the Act of 1862, which had never been repealed. Unfortunately, however, the district councils had proceeded under the District Councils Act, and that Act contained a provision that the councils must first clear their own land. That provision, however, was not in the Act of 1862. The Board had recommended the Government to place the control of noxious weeds under the Minister of Agriculture, and the question was referred to Cabinet; but, presumably, because the Government considered that the request should come from the local bodies concerned themselves, nothing had come of it. The point he wished to emphasize, however, was that the district councils should prosecute under the Act of 1862, which did not contain the provision which in their own Act was a stumbling block.

Mr. McEwin (Blyth) considered the question too important to be decided that morning. He took it for granted that the Noxious Weeds Act was not being administered, but would like to know how much harm resulted through its non-administration. So far as the Scotch thistle was concerned, it could be destroyed easily by cultivation. He opposed the motion. They had enough Government officers worrying them already. Did members of Congress know that there was one Government man out of every 11 men in the country?

The motion was lost by a large majority.

STUBBLE AND SCRUB BURNING.

Mr. A. Ramsey (Utera Plains) moved—"That district councils be empowered to fix the dates as well as hours for burning stubble and scrub in their respective districts." The objective was to place in the hands of the councils power to prevent the burning of scrub until a later date than now allowed in those districts where burning so early in the season was dangerous. Such legislation would also enable the district councils to prohibit the burning of stubble which, under existing regulations, might be burned between certain hours during any month of the year.

Mr. Nicholls (Secretary Advisory Board) stated that at present district councils had no power to alter the dates on which scrub might be burnt. It was felt that the councils should have power to prohibit the burning of stubble in their respective districts when that course was deemed necessary, and they should be empowered to prohibit the burning of scrub during the early part of February.

Mr. D. B. Butler (Butler) drew attention to the fact that in his district persons were burning scrub, &c., during the time they had crops standing in the paddocks.

Mr. C. Ricks (Cherry Gardens) considered that the Bush Fires Act should be amended to allow of the burning of scrub in the hills districts in November, February, March, or April during night or day. The present Act prevented their lighting firebreaks during the months of November, December, January, and February. They wished to burn their scrub in November. If they had been allowed to light firebreaks during last November, no doubt a great deal of the damage done by the bush fires would have been obviated. The district councils knew the local conditions, and should, therefore, be in a better position to fix the time for the burning of scrub and stubble.

The motion was carried unanimously.

EVENING SESSION.

Mr. G. F. Cleland, a member of the Advisory Board, presided.

DUTY ON IMPORTED SUPERPHOSPHATE.

Mr. F. Coleman (Saddleworth) said that he had been asked to move the following resolution:—"That this Congress of the Agricultural Bureau is strongly opposed to any duty on imported superphosphate, and requests

the Advisory Board to take such action as may be necessary make this to protest effective." The question had been referred to the various Branches, and over 20 replies had been received, each of which was strongly opposed to the proposed duty. The Saddleworth Branch was not in any particular way identified with the matter, but it had been thought that it would be well for Congress to have an opportunity of considering it. The question of imposing a duty on imported superphosphates had, he understood, been seriously considered by the late Government. The proposal, he understood, was that the duty should be 10s. per ton. The quantity imported into the Commonwealth in 1910 was 225,000 tons, and the quantity distributed over the land was between 300,000 tons and 350,000 tons, consequently an increase of 10s. per ton in the price would practically mean a tax of £150,000, which would come direct from the primary producers, as it was a tax which could not be passed on. At the recent Conference at Lameroo the general impression had been that it would be beneficial to the farmers if they used more superphosphates. Probably the reason why such comparatively small dressings were now used was because of the expense, and if that were added to the probability was that less instead of more would be used. So far as he knew, there was not a country in the world where duty had to be paid on fertilisers. A certain amount of superphosphate was imported, and it had been said that it was dumped here. He had, however, been told that that was not so. The reason why that particular phosphate was largely used was because it was a very good phosphate. The imposition of a duty on superphosphates would be a serious mistake. Already, owing to the rise in wages and the increased cost of living, it was costing the farmers decidedly more to grow a bushel of wheat than it did formerly.

Mr. W. Roennfeldt (Greenock) seconded the motion, which was carried unanimously.

THE FRUIT-GROWING INDUSTRY: ITS POSITION AND PROSPECTS.

Mr. Geo. Quinn (Chief Horticulturist) contributed the following address on "The Fruit-growing Industry: Its Position and Prospects":—

Anything partaking of the nature of a review of the progress of fruit-growing in South Australia would involve a careful scrutiny of the progress of the State as a whole. In this respect no great departure is made from the rise of this particular form of production in all newer countries of the world. In our case the pioneers brought with them the seeds or plants of the kinds of fruit familiar in their home countries, and in a few instances others—chiefly men of travel who had visited warmer climes—went farther afield in search of the products of those parts of Europe and Asia wherein the climatic and soil conditions were deemed to most closely approximate to those they found, or expected to find, beneath the Southern Cross. For a good many years after the foundation of the State, and while there were

yet no aggregations of population in cities, fruit-growing was confined almost entirely to the raising of supplies for domestic purposes. The discoveries of copper mines in various centres, with the consequent concentration of population—not directly providing its own food—gave an early stimulus to the commercial production of fruit and other garden crops. Later on came the opening up for wheat-growing of those parts of the Northern Areas over which the restricted rainfall made the growing of fruit by the farmers and township dwellers almost impossible. Meanwhile the increase of city and suburban population gave a further impetus to fruit-raising, and in the middle distance of our history as a province the fame of Adelaide-grown grapes had established a water-borne trade with Victoria, and a little later with New Zealand.

Although practically all the needs of the Victorian trade in fresh grapes have been for some years self-supplied, during the season one may yet see a reflection of this fame in the tickets displayed in the Melbourne fruit shops bearing the delusive legend "Choice Adelaide Grapes." (Laughter.) The sudden rise of the Barrier mining fields in the eighties came as a boon to the struggling fruitgrower, and this market has increased in value until last season the exports of South Australian grown fruits forwarded to Broken Hill exceeded 82,000bush.

MURRAY RIVER SETTLEMENTS.

Another of the most remarkable awakenings that this industry has received came with the advent of the Murray River irrigation colonies, established through the energy of the Chaffey Brothers. It is at the present day interesting to recall how the proposals of these enterprising Americans were viewed with incredulous pity by the older order of fruitgrowers, who charitably gave them an opportunity which it was generally considered could only end in disaster. It is quite true the Chaffey failed; but in their settlements they gave this State, and in fact all Australia, the finest object lesson in intense fruit culture yet received from any source. (Applause.) As an outcome of the recognition of the community of interests possessed and realised by the fruitgrowers in the Chaffey settlements another object lesson has been afforded, which I venture to predict shall have a wider influence on the welfare of those engaged in fruit-growing in the State than any other event which has transpired in its history. I allude to the co-operative effort, which has not only resulted in the primary producer having a voice in the fixing of the price of his products, but has regulated as well the general standard of the quality of such produce.

Fruit-growing before it becomes raised to the status of a staple industry has awaited in all countries upon the aggregation of population, either at home or near by, to provide the necessary consuming power. Usually it is one of the heralds of closer and intense settlement upon a country's lands,

With perhaps the exception afforded by Tasmania, in Australia it has followed slowly in the wake of agricultural and mining developments, which have been in turn preceded by the pastoral occupation.

THE APPLE EXPORT TRADE.

Following closely upon the good foundation given to the dried fruit industry by the Murray River irrigation colonies, probably the next best prominent milestone on the road to progress was the awakened activity given the industry by the Agricultural Bureau in the earlier years of its establishment. Through the determined advocacy of the late General Secretary, well supported by the late Mr. Thomas Hardy and other earlier members of the organisation, the business of fruit-growing took a fresh lease of life. (Applause.) The planting of apples for export was widely advocated, and the campaign against insect and fungus pests of the orchard organised upon modern scientific lines, some legal steps being taken to enforce attention to the neglected trees.

Coming closely in the wake of these efforts of the Agricultural Bureau, and as a natural corollary thereto, was the inauguration by the Government Produce Depot of the regular export trade to Europe in apples, and to a lesser degree in pears, grapes, and oranges.

Beginning in 1896 with a modest 647 cases, this trade has, with fluctuations due to irregular yields, increased in 15 years to a total of 187,701 cases last season (1911-12). Taken on the very modest basis of a value of 7s. 6d. per case, this represents a money value of £70,000.

THE FRUIT YIELD.

Arrived at the stage of its present position, your indulgence is sought whilst I quote a few figures in describing the same. The statistical records for 1911-12 show that for commercial purposes 23,214 acres are devoted to fruit trees, 1,850 acres to grape vines for fruit for table uses, and 7,406 acres of vines for drying into currants and raisins. To make these figures more expressive of the meaning contained in them, I wish to go into a few details. Calculating 100 trees per acre as a conservative basis, we possess of—

	£	s.	d.
Almonds, 2,625 acres, yielding 282 tons of nuts worth at 6d. lb.	15,766	16	0
Apricots, 2,422 acres, 165,982bush., at 2s. 6d. bush.	20,747	15	0
Apples, 9,550 acres, 583,860bush. at 2s. 6d. bush.	72,985	0	0
Cherries, 870 acres, 42,607bush. at 4s. bush.	8,521	10	0
Pears, 1,450 acres, 81,644bush. at 3s. 4d. bush.	13,607	6	8
Plums, 1,573 acres, 106,758bush. at 2s. bush.	10,875	8	0
Oranges, 2,246 acres, 220,988bush. at 5s. bush.	55,247	0	0
Lemons, 517 acres, 47,176bush. at 2s. bush.	4,717	6	0
Peaches and nectarines, 1,872 acres, 80,315bush. at 4s. bush. .	16,063	0	0
Unspecified, 373 acres, 5,533bush. at 2s. bush.	553	3	0
Bush and berry, 579 acres, 13,338bush., at 6s. 8d. bush.	4,444	13	4
Currants (dried), 2,334 tons 15cwts., at £37 6s. 8d. per ton (calculated at 4d. per lb.)	87,164	0	0
Sultanas (dried), 737 tons 3cwts., at £46 13s. 4d. per ton (or 5d. per lb.	34,400	6	8
(Gordo and Lexias, 995 tons 8cwts., at £28 per ton (or 3d. per lb.)	27,871	4	0
(Grand total	£372,764	8	8

Of the 24,077 acres as calculated above, 6,816 acres are reported as not yet in bearing. This leaves 17,261 acres of fruits other than grapes, yielding a value of £223,328 18s., or an average return of not quite £13 per acre based on the above estimated values, in respect to which I invite criticism. It may be mentioned, in passing, that the Government Statist, who takes a more liberal view of the values, estimates those of orchard and market garden crops at £376,915, and as the value of market garden crops is stated to be £95,434 during 1911-12, the orchard revenues, when added to the value of the dried fruits of the grape vine quoted above, would make a total of £430,916 10s. 8d. for the last season's operations in the production of fresh and dried fruits.

THE OUTLOOK.

The above figures convey something of an approximate idea of the position of the fruit-growing industry. And now what of its prospects?

It is when we begin to face this question squarely we realise that no longer are we an isolated province, but a unit in a great Commonwealth, and our vision must in many respects compel us to take even a wider view and become fully seized of the fact that we are rapidly assuming the position of one of many of the competitors of the world's markets. If I can read their thoughts, in the planting operations of those whose actions are worthy of consideration. the indications are as follows:—

There is a steady, shall I say somewhat slackened, pace in the planting of apples, and more particularly pears, for export purposes. Plums, with the exception of drying prunes, are not being set out at all. There are moderate plantings of peaches, chiefly of the varieties suited to drying and canning. The area under apricots is almost stationary. Almonds are being planted somewhat freely. Lemon trees are not only not increasing in number, but are becoming neglected in the present plantations, or being grafted over to oranges. The planting of oranges of the Washington Navel variety has made nursery stock of this sort practically unprocureable. Pears of the William's Bon Chretien variety for drying and canning are receiving moderate attention. The fig, owing to its coming into favor with the jam-maker, has begun to creep more into prominence of late. Nectarines which have never been abundant are practically not increasing.

RAISINS AND CURRANTS.

Turning to those grape vines, the fruit of which is used for food, planters are cautious. The Gordo Blanco, from which the ordinary *lexia* or pudding raisin is made, has long since been produced beyond the requirements of the Commonwealth, and the shipments made thus far to London are never described as being sold at "Dumping prices"—that term is relegated to the over-stimulated products of other countries which may be sent to us. The present value placed upon this grape may be estimated from the experience

of the writer who, at mid-season this winter, failed to secure 300 rooted plants from the local nurseries. Fortunately the stimulus given to the distillation of brandy has come almost in the guise of a charity visitor to the growers of Gordos.

Since about a decade ago, when Mr. W. C. Grasby brought prominently before our growers of Zante currants the advantages secured in the shape of increased yields in Greece by cincturing the stem of this vine, and the Commonwealth Government followed closely by placing a prohibitive duty upon the European grown fruit, the increase in production has gone up by leaps and bounds in this State, which has thus far produced more than half the currants grown in Australia. This frenzied haste to get rich out of currants has now given place to a feeling of uncertainty respecting what shall happen when (as it must inevitably) within the next few seasons, probably three or four, the production exceeds the consumption within the bounds of the Commonwealth. Personally, I think this spirit of caution is a wise one, for without something wholly unexpected happens we have no hope of taking the dried produce off our currant vines to Europe. I am not altogether pessimistic respecting the chances of the currant-grower, and hope no one will ridicule the suggestion that sometimes supply creates demand, which is, perhaps, a reversal of the hard and fast rule universally accepted in general economics.

The other seedless grape, the Sultana, if gauged on the basis of the present needs of the Commonwealth has yet a little time to exist and yield a profit. In respect to this fruit there is a faint hope that we may yet obtain a place in the world's markets; but this, in my humble opinion, will depend largely upon our own efforts in the direction of producing an article which is not beaten in quality by the old world centres of production.

APPLES, ORANGES, ETC.

Returning to the other fruits quoted, I am of the opinion that with the widened outlook we are not now much nearer to over-production in apples than we were 20 years ago, although the price for our produce has receded. This fruit is universally used by the rapidly increasing white races, and nothing supplants it. In regard to pears, our canned produce is equal in value to that of any country in the world, and yet is capable of much improvement by better methods of manipulation.

Prunes we yet import in large quantities. All of our dried figs worthy of the name are brought from Southern Europe, and yet every kind of fig, including the fig of commerce, thrives in this climate in a manner difficult to excel. The same may be claimed for the almond, which is as yet largely imported into the Commonwealth.

The Washington Navel orange grown along the banks of the Murray has been declared by competent authorities in London to be "the finest orange

that has ever entered Covent Garden market." (Applause.) This reputation is borne out by its inherent natural qualities—a fact fully recognised by dealers in the adjoining States, as may be noted from the shop and market values placed upon them in the eastern capitals. I have been informed by those who have been commercially interested in the shipping of this orange to London, that it is not a paying proposition. The reason advanced being, that "A loss of between 15 per cent. and 20 per cent. must be reckoned on for depreciation through decay in transit. For those landed in good order the price obtained has been remunerative, but the risk of decay on the voyage had been too great."

Accepting these statements as facts, I am of the opinion the exportation of this orange is on a parallel basis with that of the apple less than 20 years ago. The solution of the difficulty rests with the careful and consistent exercise of human intelligence and ingenuity in the handling and transport of the product from the orchard to the market. Although the opinion may be disputed, I believe that this orange in Australia, as it has in California, will practically displace all of the more prominent common types of oranges, and to do this they must be produced cheaper and in greatly increased quantities.

THE NEED FOR CO-OPERATION.

Regarding the position from a State, Commonwealth, and oversea point of view, I venture to assert that the prospects for good or ill in respect to this industry are largely in the hands of our people themselves. There are problems in production which must be met and overcome, but the problems crying most loudly for solution at the present moment are mainly connected with the manipulation and marketing of the produce of our orchards.

At a recent meeting of one of the Branches of this Bureau in a fruit-growing district a member very pertinently said, "You have given us some useful information regarding the growing of fruit, but what troubles us just now is how to sell it to better advantage." That sums up the present position in a nutshell and reveals the unsatisfactory side of the industry.

I beg you will allow me to face this question in some phases as it appeals to me. I know something of the struggles and disabilities under which the primary producers labor. In my mind it has always rankled as one of the most unmitigated injustices humanity tolerates that the men who feed the community should have as yet had little or no voice in fixing the price they shall receive for the results of their labor. The crying need for the man on the land is organisation. (Applause.)

Let them recognise the community of interest which naturally binds them together. Let the fruitgrowers be fully seized of the fact that genuine reforms do not come from those who have profits to lose by their consummation. The fruitgrowers must work out their own industrial salvation.

I know these opinions may be discounted as so much theoretical cant, coming from a publicly paid official, but projects seemingly of an infinitely less likely character have crystallised into actual working factors in our midst within recent years. Who would have dared, 25 or 30 years ago, to say that such a motley heterogeneous class of men as Australian shearers and bushworkers could have been organised into a sufficiently cohesive body as to practically dictate terms to such an immense and widely influential interest as the pastoral industry.

The fruitgrower must begin to reform his industry as all other adherents to any fixed reform have done by sinking certain immediate personal advantages to enable the good of the whole body of fruitgrowers to be realised. In other words, the advantages and disadvantages must be pooled to enable the former to be magnified and the latter to be more readily overcome. No system of co-operation has been achieved without struggle and sacrifice, and one cannot hope that the case of the fruitgrower will prove an exception. Personally, I see no possible chance of the fruitgrower obtaining permanently a fair share of the results of his labor without he becomes embodied into the closest and most far-reaching co-operation.

The producers of dried fruits are not only in this, but in the adjoining States, being gradually drawn together with results of a gratifying nature to their industry in the shape of regulating the price and standardising the quality of their produce. Theirs, it will be claimed, is an industry which has developed under the shelter of a tariff wall, but that cannot discount the value of the organisation built up; and when the time comes to meet the crisis which a home tariff cannot altogether surmount, the lessons in association learnt will prove a tremendous factor in overcoming the difficulty. Let us not forget that it is only by constant vigilance any industry can be maintained on a satisfactory basis. In the question of oversea export there is need for fruitgrowers, not alone in this State, but throughout the Commonwealth, to unite to influence and understand each other, to counsel Governments, and to approach merchants, shipowners, and other bodies who, though necessary to the well-being of this industry, are ever on the alert to take advantage of their disunion to absorb the lion's share of the value of what the fruitgrower raises. I repudiate any idea of setting one section of the industrial community against another section—that has been brought already into existence by the stress of the trade—but to secure fair play the competitors must stand on equal terms.

In the export trade the standardisation of the fruit in variety, maturity, grading, packing, and general condition is a crying need, and this cannot be accomplished without organisation, and I may say such organisation should not be confined to this State alone. The time is passed for parochialism for this trade whose federalism has outstripped the boundaries of politics.

A STRIKING ANOMALY.

In matters of purely local trade it is only by organisation that a better system of distribution of our orchard products can be achieved. There is much radically wrong with a system which allows tons of the best plums—equal to the finest the world produces—to rot upon the ground because the grower cannot obtain more than 1s. per bushel for them, when at the same time in our Northern townships and on the farms within a couple of hundreds of miles such fruit costs the consumer 3d. per pound. (Applause.) It is a pertinent question to ask for the reasons why, in our Northern Areas, the storekeepers stock their shelves with Tasmanian jams made in some instances from kinds of fruits which that State does not produce or produces very scantily, and which in this State grows so abundantly that the grower cannot obtain a payable price for them.

A BEGINNING IN ORGANISATION.

In one district a start has been made over a few seasons to pack and export apples on a co-operative basis under a district brand. The Commerce Act examiner will tell you that these lines give no trouble to him, because from one end of the season to the other they are uniform in grade and packing. In a suburban locality a co-operative jam and fruit-preserving factory has made its appearance. Let me ask fruitgrowers in all seriousness to give it support, and if it is not properly conducted lend a hand to overcome the difficulty. Get all those country storekeepers who stock jams from outside sources to become shareholders with you and thus secure their keenest interest in pushing your goods at the smallest margin of expenditure on middlemen. In conclusion, I wish to emphasize the statement that the only hope for the fruitgrower lies in the co-operative distribution of his produce, whether in a fresh, dried, or preserved condition. (Applause.)

THE DISCUSSION.

Mr. W. H. Waters (Renmark) said that Mr Quinn had stated that the output of dried sultanas was 737 tons last season. He thought that Renmark alone produced that amount.

Mr. Quinn—That is the output from Renmark. There is very little produced anywhere else.

Mr. Waters asked if Mr. Quinn did not think if the packers wore gloves when packing for export that oranges would carry well and keep well after arriving at their destination. He had exported oranges for the last four seasons, and not only had they arrived in absolutely tip-top condition, but had kept for months. He put that down entirely to careful handling.

Mr. Smith (Angaston) said that over-production as regarded currants and sultanas had already been reached. He would like to know if Mr. Quinn knew any cure for die-back in apples and Duchess pears. He knew a piece of

black level soil at Angaston which had been planted with apples, but in four or five years the trees had died. It was replanted with pear trees, but these had also died.

Mr. Quinn said he entirely agreed with Mr. Waters as to the necessity for great care in handling oranges intended for export. Up to the present that necessity had not been recognised by some growers. He was obliged to Mr. Smith for the information regarding currants and sultanas. He happened to know the piece of land at Angaston to which Mr. Smith had referred, and from its outward appearance did not think it was deficient in nitrogen. It seemed as if the soil contained something not suited to apples and pears.

Mr. Ricks (Cherry Gardens) said one difficulty fruitgrowers had to contend with was the fact that they did not get proper carriage on the railways.

Mr. J. J. Cormack (Amyton) supported Mr. Quinn's proposal that the fruitgrowers should form themselves into co-operative bodies.

Mr. Laffer said that there was no need to make any complaint in regard to the carriage of fruit on the railways so far as this State was concerned. He thought the railway officials helped the fruitgrowers in every possible way. Louvre trucks were not necessary when fruit was carried only a short journey, but they were necessary for long journeys, and the Government had provided quite a number of those trucks for the carriage of fruit and vegetable produce.

Mr. Salter (Angaston) agreed with Mr. Quinn's views in regard to the need for co-operation among fruitgrowers, but it was extremely difficult to bring that about. One difficulty was to get them to hold together as regarded prices. However, he believed that had been brought about in America, and it would have to come in South Australia.

Mr. Jackson (Kingston) asked what was the cause of shothole in apricots.

Mr. Kimber (Northfield) said that an organisation known as the Fruit-growers' and Market Gardeners' Association was being formed near the city, and now had 500 members. He therefore thought there was a chance of an agreement being arrived at as to the prices of fruit. Mr. Quinn had referred to the Co-operative Jam Factory, and he was glad to be able to say that that factory had been so successful in the first year of its existence that tenders were now being called for its enlargement.

Mr. Arundel (Greenock) asked if grapes grown in the Barossa district were of as good quality as those in the hills near Adelaide.

Mr. Quinn said shothole might be caused by one of several fungi. It was a disease which could be prevented to a great extent. The remedy was to spray the trees with Bordeaux mixture just when the color of the flower was commencing to show. With regard to the richness of grapes in the Barossa district as compared with those grown on the Adelaide plains he could hardly speak; but as a rule the grapes on the Adelaide plains were

grown in richer and better soil than those in the Barossa district. The tendency, therefore, was that they made a more attractive table grape, but very possibly the grapes grown at Barossa would be richer in saccharine.

A visitor desired to know whether spraying with arsenate of lead would result in the destruction of curculio beetle.

Mr. Quinn replied that in one case where nursery stocks were heavily covered with arsenate of lead the beetle disappeared; but in the case of experiments carried out in the South-East, spraying was found to be ineffective.

Mr. Cleland (Advisory Board) pointed out that fowls would get rid of the beetle.

PROBLEMS CONNECTED WITH THE SHIPMENT OF FRESH FRUIT TO OVERSEA MARKETS.

Mr. G. R. Laffer (Vice-Chairman of the Advisory Board) read the following paper on the above subject:—

In dealing with the matter under consideration, one is impressed with the fact that production of fruit has increased enormously during the last few years, and it can be said with safety that the industry has reached such large dimensions that it is imperative that a large proportion of what is grown must be exported, as the quantity produced is far in excess of what is required for local consumption.

In Australia our season of production is the very opposite of those countries in the Northern Hemisphere, and although cool storage has done much to extend the season in which fruits can be held in condition, there seems to be a limit to the time in which it can be stored and sold at a profit; consequently we find a short season in the spring of those countries when the supplies of local stored fruit becomes depleted, and they have to look elsewhere for supplies. That season is only a short one of about two and a half months, and this is the period for which fruitgrowers in Australia have set themselves the task to supply the requirements of those markets. With that end in view, very large areas of land have been planted with those varieties of apples and pears which experience has proved to be most suitable for the requirements of European and other markets. As fruit trees begin to produce profitable crops at five years after planting, it will be seen that it is a matter of the very greatest importance to those engaged in the industry, and also to the welfare of the several States in the southern portion of Australia where fruitgrowing plays such an important part in the settlement and development of the country, that the markets of the world where Australian fruit can be profitably absorbed should be fostered and organised to their very fullest extent. Not only are we faced with the fact that many young orchards are coming into bearing, and the number is likely to increase very much during the next few years, but it is also safe to say that orchards are now much more productive than they were a few years ago. Owing to

the complete success of arsenate of lead as a spray, the loss through wormy fruit is now not often more than 5 per cent. where previously it was from 40 per cent. to 60 per cent., so that not only are the trees more profitable, but the area has increased very much.

FRUIT PRODUCTION.

That the industry should receive every assistance in overcoming the difficulties with which it has to contend by the Governments of both State and Commonwealth I am sure will be conceded by all. (Applause.) Fruit-growing is essentially a closer settlement industry, and employs a larger proportion of labor on a given area than any other rural industry; it occupies areas of land which in many respects would be of little use for other industries, and provides men of limited capital with a means for providing homes for themselves and their families in humble content and happiness. It was estimated three years ago that orchards and gardens in this State raised produce worth over £700,000 for that year. That fruit grows to a great degree of perfection in this State I am sure will be readily conceded, and if, with the very limited areas now under cultivation, fruit and other products can be produced worth nearly three-quarters of a million pounds in a year, one is impressed with the enormous possibilities of the extension of the fruit areas. To me it seems there is scarcely any limit to our production in this respect; but we are faced with the fact that there are limits to profitable markets for our produce.

That the State Government has done a great deal for the industry must be admitted, and a great deal more would be done if the growers would only combine and organise in their own interest, and I maintain that sooner or later they will be forced to do so. Many of the difficulties which now beset the industry would be overcome if the growers would only be true to themselves.

VALUABLE GOVERNMENT ASSISTANCE.

Growers in this State have at their disposal the splendid facilities of the Produce Export Department at Port Adelaide, where fruit is received and pre-cooled before shipment at a very nominal charge when one considers the services given. In addition to this, the Government have provided, for the purpose of looking after producers' interest in London, the Trade Commissioner (Major Norton), who personally supervises the disposal of every consignment of produce sent to him. Yet I have no hesitation in saying that it is to the fruitgrowers' discredit that his services have not been more fully used in connection with the disposal of South Australian fruit on the European markets. That all growers and shippers indirectly gain by the Trade Commissioner's presence in London I fully realise, as his very presence there has had a general toning up in the handling and disposal of South Australian fruit.

To me there seems several distinct reasons why the Trade Commissioner's services are not more fully availed of. The first is to be found in the fact that the Produce Department do not canvass for business, but simply do the work for those who choose to come and ask them to do so. Secondly, there is some feeling among growers that they cannot rely upon the Produce Department being able to obtain the necessary space, particularly in early or favorite boats.

THE SPACE DIFFICULTY.

Thirdly, the fact that certain firms who act as agents for steamers carrying fruit are also produce agents, and canvass for business and have the allotment of space within their hands, has certainly not tended towards the independence of the grower, who, in many cases, feel that they have a better chance in having the space requirements allotted if they ship through these firms.

Under the present system, where specking space is allowed by private firms, the Produce Department or any shipper putting in applications for actual space required is likely to find themselves with a *pro ratio* allotment, which may be one-third, or even less, of actual requirements. So that if it can be urged against the Produce Department that growers are not sure of getting their space requirements allotted if they propose to ship through them, it is surely due to the faulty system prevailing by shipping companies allowing private firms to speck the space.

It was rumored last year that one firm in Adelaide applied for space for about 180,000 cases, and only shipped a little over 20,000 cases. That firm had not a possible chance of controlling 180,000 cases, as the full export for the State was only about that quantity; but coming in on a *pro ratio* basis they got control of a large quantity of space, and consequently growers had to go to them for their requirements, and the fruit was handled by that firm's representative in London. This is an exceptionally large application, but the system is that which is adopted by most agents.

Shipping companies should not allow agents to control the space until they have given growers every opportunity of taking it up. They should recognise their responsibility to growers of produce for whose custom they are catering, and, therefore, should demand some evidence that applicants are accredited agents for certain growers who have certain quantities to ship.

Tasmania being off the regular route of steamers, shippers there have protected themselves by making forward contracts for space, and thus we are all forced into the early taking up of space, *i.e.*, applications have to be made in October and November for fruit which will not be shipped until March and April. It is questionable if there is any necessity for this now, although it may have been necessary in the early days of the trade. Fruit is carried by regular lines of steamers. The boats come to Australia. They would in any circumstances pick up the fruit. Therefore, no reason can

be seen why shipping companies should require any more lengthy application for space for fruit than they demand for butter, shipments of which from South Australia are arranged not earlier than 17 days before date of shipment. The fruit business should not be any harder to arrange than the butter.

Even after growers have made application for space and have had it allotted to them by shipping companies, the space has not always been available when the boats have reached this State. This difficulty was prominent the season before last, when growers who had entered into definite space agreements found when the boats reached Port Adelaide that their space had been filled in the other States, and the fruit which they had provided ready packed for shipment was thrown back upon their hands. This was particularly the case in some of the early boats, and created a block at port practically right through the season, and eventually resulted in heavy loss to shippers. This is distinctly unfair, as, having entered into definite contracts, had the fruit not been forthcoming shipping companies would have looked to growers to pay dead freight.

THE CARRIAGE OF FRUIT.

One of the most unsatisfactory aspects in the export trade is the very unsatisfactory condition in which much fruit reaches its destination. While I am not going to say that the shipping companies officers are entirely responsible for this, still there has been, on many occasions, very distinct evidence that proper temperatures on the voyage home have not been maintained. This is very important, apart from the question of condition. It has been proved conclusively that bitter pit, a disease affecting some varieties of apples, is practically developed on the voyage home by fluctuations in temperature. Condition is really the governing factor in the successful development or otherwise in the shipment of fruit to oversea markets, so that growers have a right to demand that as they pay a high rate of freight for cool storage on the journey to London and elsewhere every care should be taken to ensure that the cargoes should be landed in good condition. Not only does bad condition mean lower prices for the particular shipment involved, but it certainly has a depressing effect upon the shipments that follow.

One of the most important points to be considered in the export trade of fresh fruit is certainly "temperatures." There seems very distinct evidence that much of the fruit is carried on the voyage at too high a temperature. I believe the regulation is now about 36 degrees to 40 degrees, while all experience seems to prove that for apples 33 degrees to 35 degrees is right; and for pears, 31 degrees to 33 degrees; and in connection with temperatures, it is very necessary to have proper air circulation.

PRE-COOLING.

It is also very important to consider the question of the temperatures of fruit when received by the steamers. Personally, I am a strong advocate that all fruit should be pre-cooled before being placed in the ship's chambers. If that were done, even temperatures could be much more easily maintained on the voyage home, and faults in condition could be placed upon the shoulders of those responsible for the defect. If the temperatures were watched and maintained on the voyage we should hear very few complaints of bad condition from the European markets.

NECESSITY FOR ORGANISATION.

As the export of fruit from Australia has passed the experimental stage and has now become a matter of trade and commerce, surely it should be the aim of those engaged in the industry to foster and organise it to its very fullest extent. I know that it has always been a most difficult task to get producers to combine, even in their own interest; but wherever it has been done on proper lines it has been greatly to their own benefit. Often the grower is not a good business man, and may have an exalted opinion of the quality of what he produces, and makes his own grades, which may be right or wrong, or thinks his brand becomes known on the London markets, and that he gets better results than his neighbour. All this may be true in some instances; but if the trade is going to expand and take its proper place as a commercial enterprise, all this has to be knocked out. The multiplicity of brands and grades is the curse of the fruit business. Standardisation of grades and brands begets the confidence of the buyer. Experience teaches that it is ever easier to sell large quantities of standard grades, and to be able to repeat orders of the same grades and qualities as the different boats reach the market, than it is small parcels from different shippers of promiscuous grades and qualities. When growers begin to realise this truth and to act upon it the trade will become more satisfactory and profitable.

THE FIRST ESSENTIALS.

The very first essential will be the establishment of packing-houses in positions centrally situated to the producing areas where all the produce from a district will be merged and packed in uniformity. Growers should also realise that it costs as much to pack and export inferior fruit as it does the best quality, and that the former, in addition, has a depreciating effect upon the market, so that nothing inferior in quality or less than 2½ in. should be sent. Whichever State adopts these precautions and methods will, to a very large extent, create confidence and capture the most beneficial trade and will put much extra money in their own pockets. At present much fruit, not sufficiently mature, is being sent early in the season. The same complaints come back every year. The inspector should have power to reject fruit with this defect.

SOUTH AFRICAN COMPETITION.

We in Australia must realise that we have a very serious competitor in South Africa. Victorian nurserymen were very fond of boasting about the quantity of trees they sent to South Africa ; but we have come to the stage when growers here must realise that those trees are beginning to produce their crops and are now increasing. Reports recently received show that the Government there are assisting the growers by engaging their space requirements. Their freight is much less than from Australia, the voyage being only about half as long, and being nearer the world's markets they can send soft fruits with comparative safety.

The natural disadvantages in Australia are great. We are farther from the world's markets than any other country producing similar commodities ; consequently the journey home is longer and more expensive. We have, in addition, to pay higher wages and work shorter hours. With these disabilities, therefore, we cannot afford any leakages, but must steadfastly set our face for greater efficiency and economy in handling. At present agents' charges are 5 per cent. on gross results London, less London charges ; and the selling charges are also 5 per cent. London.

COST OF PRODUCTION AND HANDLING.

One of the most serious aspects of the trade from the growers' point of view is the ever increasing cost of production and, more particularly, of handling this end. That the industry has nothing to thank the Commonwealth Government for has been proved over and over again. While they seem anxious to deal with wages and conditions of employment, it seems they never seem to consider whether an industry which is a rural one can stand the continual fretting away of the margins of profit which, for various reasons, have ever been small. The highly protective duties press heavily upon the fruit industry, as it does upon most rural industries which look to the markets of the world to absorb surplus productions. It is argued that we have our own local markets to ourselves, which is true, and we all fully appreciate them ; but the fact remains that you cannot regulate prices even to the paying stage when commodities are being produced in excess of local requirements. Without the outlook of supplying other markets than our own, the industry will never reach the importance and dimensions that it is capable of reaching if treated in a fair way.

The ever-increasing cost of living is constantly being urged as a reason for higher wages and more protection. The manufacturer of commodities and the man that handles them is able to pass the increased cost on, and the producer is the man on to whom they are passed ; but he is unable to protect himself, and, in addition, knows that owing to increased production prices are receding, and the world's markets are going against him. One great lesson which has to be learned in Australia is that if an article is going to cost

more to produce than it will bring upon the world's markets, it is not going to be produced. It is ever a wise policy for the individual as well as the State to stimulate the growth of productions for which your land and country is best suited ; but sooner or later the producers of Australia will wake up and refuse to be bled for the purpose of creating artificial conditions which pertain to the detriment of rural industries at the present time.

The requirements of the fruit industry have never been properly inquired into or treated fairly under the tariff. The present Commonwealth Government, under the plea that all paper required for wrapping fruit should be cut in Australia, imposed a duty of 35 per cent., which was a direct tax upon the export trade to the extent of 6d. a ream, and was just recently removed because of its ridiculous nature. But in the place of it the duty on timber, which is practically all imported for box-making for the export trade, was raised first from 3d. to 1s. 9d., and last year from 1s. 9d. to 4s. 6d. per 100ft. The result of this was that cherry crates being used at the time of the increase for Western Australia cost 2s. 6d. each ; the price was immediately raised to 2s. 8d., and plum boxes, into which 2s. worth of fruit had to be put, from 8d. to 8½d. each ; and all other export cases in proportion. And now there is a movement on foot in Melbourne by box manufacturers to increase the duty from 4s. 6d. to 10s. per 100ft., entirely ignoring the fact that for boxes it is possible to use much refuse at the mills, thus enabling the fruitgrower to get his boxes cheaper. But the action of these duties will be that all boxes will have to be cut from large timber of sound, importable quality.

Surely there must be an end to this insane policy, because it is killing the goose which lays the golden egg. The wheatgrower often complains that the merchant treats him unfairly over his bags, which cost only about 5d. each into which he is able to empty 12s. worth of his produce ; but the fruit-growers' package costs a shilling into which 3s. worth of produce has to be very carefully packed, and that package has to be entirely given away.

TRADE WITH AMERICA.

In a recent address His Excellency the Governor drew attention to the great trade changes likely to take place with the opening of the Panama Canal. Although this will not bring Australia nearer the European markets, it certainly should be the means of opening up an extensive trade in fresh fruit with the United States of America, and to a lesser extent with Canada as well. Markets must be found, as the area coming into bearing is increasing rapidly. Whether the market can be extended very much in Europe without lowering the price is doubtful ; whether a cheapening of transport and handling is possible remains to be seen. I believe it can this end by proper organising, and I believe uniformity will return increased values on the world's markets ; and also that if supplies were under more central control on those markets

the cut throat conditions at present prevailing, particularly when markets are over supplied, would not be felt so acutely.

I would earnestly ask growers to give their careful consideration to some of the problems suggested, and also to work together for the betterment of conditions. I have suggested what I consider some means by which this end can be obtained. We all know that a very large quantity of the fruit shipped last season to the European markets did not, for various reasons, return a payable price to the grower and shipper. The grower cannot go on producing and selling at a loss. We have the example in the butter industry of what uniformity of quality has done, and I believe that in the fruit industry equal results could be achieved if the growers would only take the matter up in the right spirit.

SMALL APPLES.

Mr. Quinn exhibited some apples, little larger than marbles, that were grown in South Australia, exported to England, and returned to the State. The Commonwealth Government, he said, had, by the Commerce Act, done a great deal in the way of improving the export fruit trade. The Act, however, did not prevent the export of small apples. If apples were only half grown, and they were branded "Under 2½ in.," the inspectors were not empowered to prevent the shipment. When, however, they had a little black spot on them, it was impossible to export them without marking that fact on the cases. He regretted that they were not in a position to prevent the export of inferior fruit. Last year, during February, Rome Beauty and other late varieties of apples had been shipped. He expressed the hope that fruitgrowers would use their influence to alter the state of affairs at present existing in connection with the Commerce Act.

Mr. S. R. Smith (Angaston) said it was disgraceful that growers should send fruit of the nature shown by Mr. Quinn oversea. If the fruitgrowers followed the suggestions of the writer of the paper material good would result to the industry.

Mr. Laffer, in replying, said that Mr. MacAlpine had stated that he had proved that bitter pit was practically created by the fluctuation of temperature to which export fruit was subjected in transit.

VOTES OF THANKS.

Mr. D. L. McEwin (Port Pirie) moved and Mr. A. J. Wedd (Mount Gambier) seconded a vote of thanks to the officers of the department, and the writers of the papers, which was carried with acclamation and responded to by the Director of Agriculture (Mr. W. Lowrie, M.A., B.Sc.).

CONFERENCE OF HILLS BRANCHES.

The Annual Conference of the Hills Branches of the Agricultural Bureau was held at the Institute, Meadows, on Monday, October 21st, when the Department of Agriculture was represented by the following:—Hon. T. Pascoe, M.L.C. (Minister of Agriculture), Messrs. F. E. Place, B.V.Sc., M.R.C.V.S. (Veterinary Lecturer), P. H. Suter (Dairy Expert), J. Miller, C. J. Tuckwell, G. R. Laffer (Members Advisory Board), and G. G. Nicholls (Secretary Advisory Board). In addition to a large number of visitors, the undermentioned gentlemen attended as delegates from the following Branches:—Uraidla and Summertown—Messrs. W. Pappin, E. Hart, N. Cobbledick, E. Hawke, L. M. Collins, W. Nicol, W. Squires, G. Prentice; Mount Barker—W. Pearson, D. G. Monfries, H. N. Bell; Woodside—H. F. Rollbusch; Meadows—J. Stone, W. M. Milligan, B. Usher, T. B. Brooks, T. Usher, T. E. Vickery, T. W. Vickery, J. Catt, G. T. Griggs, J. R. Morriss, T. Nottage, A. F. Ellis, S. Smith, and Rev. J. H. Williams; Clarendon—A. A. Harper, A. Harper, E. A. Harper, A. Phelps, H. C. Harper, T. B. Brooks, T. A. Shiedow, E. Dunmill, A. L. Morphett; Cherry Gardens—J. Lewis, E. Broadbent, J. Tozer, T. Jacobs, jun., H. Lewis, S. W. Chapman, T. Jacobs, C. Ricks; Longwood—W. H. Hughes, T. G. Oinn, E. A. Glyde, J. C. Blakely, A. W. Chiles, A. F. Furniss, W. Nicholls; Dingabledinga—H. Allen, F. DeCaux; Ironbank—J. T. Morgan; Morphett Vale—H. Sprigg, A. C. Pocock, L. F. Christie, E. E. Hunt, A. Benny. The chair was occupied by the President of the Meadows Branch (Mr. G. Ellis), and arrangements, which were in the hands of the local Branch, were excellently carried out by Mr. W. H. Bertram, the Hon. Secretary.

OPENING ADDRESS BY MINISTER.

The Minister of Agriculture, in declaring the Conference open, remarked that the large attendance at the meeting was a striking evidence of the desire on the part of the producers to obtain as much information as was procurable in regard to their callings. It was now generally recognised that the success of the State depended on the measure of success which attended the efforts of the primary producers, and therefore it was well for them to bear in mind that everything that was done to advance their interests was to the benefit of the State. In South Australia there were great variations of soils and climatic conditions, and because of this a person who could speak with authority with regard to the farming practices most suitable for one particular district was likely to be almost ignorant of the most economical workings for other localities. A comparison of the Hills districts where, he understood in a good many cases they could secure a livelihood from say eight

to ten acres, with that part of the north where he had been farming, where 1,000 acres was considered necessary, exemplified this. In the latter case they could do little in the way of intense culture, being practically limited to wheat combined with wool growing. The Hills districts embraced probably the most closely populated agricultural areas of the State, and it was therefore doubly important that they should work their land in conformity with the most up-to-date practices. Whatever they produced should be the very best of its kind. As an instance, let them consider dairying, which was so well adapted to the district. It was not more expensive to keep good cows than indifferent animals; but still there were those who were content to ignore the necessity of testing and culling their stock. His attention had lately been drawn to some figures bearing on this subject. A South Australian dairyman who systematically undertook the testing and culling of his herd, had 118 cows which averaged 437galls. per head for the year. Of this number 24 averaged over 2galls. daily during the period they were in milk; 70 in all averaged over 1½galls. daily, while 10 averaged under 1gall. While the average of the herd could be considered satisfactory, there were in it 30 cows which were returning no profit. The support given Cow-testing Associations in such countries as Sweden and Denmark was very strong, and the results of 10 years working of one Swedish club were interesting. Starting with selected cows, averaging during the first year 689galls. and a butter yield of 236lbs., they had by the end of the tenth year raised the average to over 1,000galls. and the butter yield to 345lbs. The test in the last year included 639 cows. Equally careful working with their fruit-growing would result in equally satisfactory improvements. During the last year, when so much damage was wrought by bush fires, the trouble was intensified by the fact that in many cases the grass had been allowed to grow between the trees. Had it not been for this probably only the outside rows would have been scorched, as he did not believe it possible for fire to travel any distance through a cleanly cultivated orchard. He was very pleased to note that the orchards he had passed on the way out that morning were well cultivated. Facts like these should impress on them all the necessity for good cultivation in their orchards. The State was dependent on oversea markets, and producers should ever remember that the only way they could successfully compete with other countries was by exporting only that which was of the first quality. Points such as these needed to be brought under the notice of agriculturists, and there was no better means of doing this than by the holding of such conferences as this. He expressed the hope that a pleasurable and profitable time would be spent by all, and declared the Conference open.

ROTATION OF CROPS AND SHEEP.

This subject was dealt with in the following paper by Mr. H. V. Sprigg, of the Morphett Vale Branch:—"To some it may appear that the title of the

paper includes two diverse subjects, and it is chiefly for that reason I have chosen it, as I feel certain that no complete and efficient system of mixed farming can obtain without a combination of the two if we are to retain, or rather to increase, the fertility of our lands and keep them in good heart, which should always be our main objective. When the fertility of the land is allowed to be run down by any method of farming, no matter how large the immediate returns may have been, we are simply deducting them from the capital value of the farm, and that is bad farming. This paper is meant to apply particularly to those districts south of Adelaide, with a rainfall of 20in. and over. Sheep on the farm must be looked at from a different point of view from sheep on a station. On the station the land value is low, and the wool is the main product. On the farm the land value is high, and the lamb and mutton form the main products—the wool may be regarded as the by-product—consequently I consider the crossbred ewe, preferably the Lincoln-Merino of good frame and robust constitution, crossed with Southdown or Shropshire rams, the best for farm purposes. There must always be differences of opinion as to which is the best breed; but whatever the breed be sure the sire is a true bred one, and that the dam has a strong roomy frame and robust constitution. We are all familiar with the direct earnings derived from sheep the lamb, mutton, and wool—and so I will deal with the indirect benefits. To begin with, I regard a flock of sheep as the cheapest, best, and most efficient ‘agricultural implement’ a man can have on his farm. It works itself and pays the farmer for allowing it to work. It cleans up the fallow and weeds and fertilises the land at the rate of about 3lbs. of liquid and solid manure per day, adding the essential humus to the soil, and in combination with a proper system of crop rotation will bring so-called worked out lands to a high state of fertility. Much of the land in the south has been continuously growing cereals alternately with bare fallow. This must in time exhaust the soil of humus and lessen its fertility. A year in grass will greatly improve this rotation; but what is absolutely essential to maintain the fertility is the inclusion of some legume in the rotation. A leguminous crop draws on the plant food supplies of the soil in different proportions from cereals, and also has the power, with the assistance of bacteria, of fixing some of the air nitrogen in the soil, and so adding to its fertility as well as partially resting it from a cereal production point of view. Now, I doubt if bare fallow is a paying proposition in this district when it is not necessary for water conservation purposes. We often suffer from too much water during the winter as from too little, and the returns from bare fallow do not compare favorably with the returns from a legume and cereal crop in rotation. The best rotation for this district is peas, wheat, barley, or oats, and two years in grass, the barley or oat stubble being harrowed or disked, and a little oats or barley, as the case may be, broadcasted over it, thereby yielding good early sheep feed. When rape

can be successfully grown it may be used in the same order in the rotation as peas, and it can also be used as a catch crop on the barley or oat fallows. With favorable summer rains it frequently gives good returns. For peas the land must be well ploughed and broken down to a fine tilth. For the following wheat crop good cultivation only is necessary. I prefer disking, and as the ground is left loose and friable after the peas no more work is needed to prepare the seed bed. The wheat stubbles will require ploughing for the barley or oats, and should be worked to a good tilth. The last two years of this rotation are completed by harrowing or disking in a catch feed crop on the stubble and a succeeding year of grass. This will give three cash crops—peas, wheat, and barley—and two feed crops in every five years, which means that with the sheep flock it earns every year. With a judicious use of chemical fertiliser the land should be in as good or even better heart at the end than at the beginning of the term, and will also have returned a larger income than would be the case with a bare fallow system. To get the best results from sheep the farm must be subdivided into paddocks proportionate to the size of the flock, that is, paddocks that can be fed down in a few weeks, thus permitting the feeding off of the grass paddocks in rotation, and also feeding off the growing crops when required. In this district cereal crops can be fed off up to the end of August, and with dirty or strong-growing early crops with a decided benefit. Weeds can be kept in check and turned into money by the sheep. A pea crop in the rotation will clean the land as well as fallow."

OTHER VIEWS AND QUESTIONS.

Mr. G. Griggs (Meadows) inquired what manure was most suitable for application to grass land?

Mr. Sprigg considered superphosphate, with perhaps a little lime, the most profitable dressing.

Mr. W. Pearson (Mount Barker) desired to know whether rape had been successfully grown in this district. His experience was that it was a risky crop to sow.

Mr. Sprigg thought rape should be grown as a catch crop. If good rains fell it would be generally found that the rape returned a good yield.

Mr. T. Jacob (Cherry Gardens) asked how it was possible for sheep to increase the fertility of the soil when the whole of the animal was built up from what was taken from the soil. A property adjoining his holding had for many years carried sheep. The land had not been artificially manured, and he was certain that it was by no means as fertile at present as it had been 30 or 40 years ago.

Mr. W. H. Hughes (Longwood) contended that the ploughing of the land did a great deal in the way of improving the pasture. If sheep were run

on it for very long it became trodden down too hard, and the grass crop was not so good.

Mr. L. F. Christie (Morphett Vale) was fully persuaded of the value of sheep for the purpose of keeping down weeds on the fallow.

Mr. F. A. Shiedow (Clarendon) believed that a great deal of good was done by putting sheep on to land immediately after the harvesting of a pea crop. They picked up peas which had been shaken out, cleared out weeds, and left the land much cleaner. He thought that where sheep were run into a pea paddock they would so increase the fertility of the land that it would be possible to grow a crop without the addition of artificial manures. During the last few years he had cleared a large area of land, and he found that by allowing a small clump of trees to remain on bare knobs he would cause the sheep to camp there. This resulted in these portions of the area being changed into fertile land.

Mr. B. Usher (Meadows) would not recommend turning sheep into a full crop of peas, as they travelled a good deal, shook out peas, and trod them in. He advised the harvesting of the crop and then allowing the sheep access to it.

Mr. W. L. Summers (Secretary Minister of Agriculture) said the answer to Mr. Jacobs' question depended very largely upon the meaning placed on the term fertility of the soil. He took it as used by Mr. Sprigg to mean the ability of the soil to produce crops, and in this sense the judicious grazing of the land in a system of rotation as outlined had been shown by experience in many countries to maintain and even increase the fertility of the soil. Although the soil might contain less plant food in a given depth, at the same time the cultivated depth contained more food in a form available to the plant. Any soils in the district contained sufficient plant food to grow good crops, but it was necessary to get this into a condition in which the plant could make use of it. That bare fallow could to a certain extent be dispensed with in these districts was proved by the experiments of the department on Mr. T. Pengilly's farm at Aldinga, where wheat after rape had averaged about 20bush. per acre during four or five years; a higher average than obtained throughout the district off fallowed land. On the same farm rape and peas had been grown successfully for a number of years, and it was interesting to observe the large increase in area in this locality that was now cropped with peas prior to the hay crop. Mr. Pengilly had also carried out a series of experiments in the feeding off of barley, rape, and rye for several years, and he believed these crops had carried on the average the equivalent of four sheep to the acre for the whole year. These green crops were of course available only for a few months, but, as it was best to feed off quickly, as many as 75 sheep per acre were grazed on them for short periods.

Mr. D. G. Monfries (Mount Barker) advised the feeding off of peas with lambs just when the crop was ready to harvest. In cases where the peas

had been stacked and then fed it was found that they did not do so well. Messrs. Pope Bros., of Mount Barker, emphatically stated that they had secured the greatest returns from lambs turned straight into the crop.

Mr. W. Pearson (Mount Barker) strongly warned members against depending too much on rape. He had tried it for six years in succession. At the Meadows he had put it in on three occasions on land that had previously grown an excellent crop of hay, but the rape was a complete failure. At Mount Templeton he put in 60 acres, and the crop did not even color the paddock. White mustard was a reliable crop. On one occasion he sowed this mixed with rape in equal proportions, and while it returned an excellent crop, the rape did not come up. Lambs fed on the white mustard had averaged about 46lbs. per carcass for export. Wherever sheep were kept on the farm and grazed judiciously they improved the producing capacity of the land. Close grazing for a number of years would certainly impoverish soil. If they cultivated it, grew a cereal crop on it, and then put on sheep they would increase the yielding capacity.

IMPROVEMENT OF GRAZING PADDOCKS.

Mr. H. F. Rollbusch (Woodside Branch) read the following paper on this subject:—"In the case of many of the grazing paddocks in this district very often there is more bare land than grass showing, the roots even having disappeared through overstocking. The farmer does not appreciate the destruction of the heifer calves from his good cows, but in sparing them he gradually accumulates more than he can properly provide food for, especially when a season such as the present is experienced. The result is that where some years ago pastures were covered thickly with a luxuriant growth of grass the herbage is now short and scanty. It is desirable, therefore, in the interests of our pockets as well as for our pleasure, that we should do something to promote conditions that will improve the growth of the grasses. It may be necessary in the first place to reduce the number of stock, but in some cases the paddocks are in such a bad state that it would take a long time to restore them by merely spelling them. It would therefore be necessary to put something into the ground to stimulate the growth. When cropping land we add manure unless it is exceptionally good soil, where a rotation of crops may be sufficient, but many expect the grazing land to go on yielding year after year, to be continually eaten off with no return made to the soil, some even gathering up the droppings from the stock—even this small return being denied the soil. There are some, however, who have awakened to the fact that something needs to be done, and are manuring on a small scale, chiefly with grass manure, and no doubt this should prove a benefit; but we cannot expect this to suit all localities or soils. It may be necessary to experiment with different manures, to find out which is the most suitable for our soils, unless we have it analysed. I think that bonedust is the best

all-round manure, and one very suitable for this district, as I have seen the good results that it has given, not only for one year, but many. Twenty-three years ago I ploughed up a piece of land and planted part of it with potatoes and put a little bonedust with each set. The paddock was then left for grazing for over 20 years, and every year when the grass grew it showed not only a better growth on the whole piece where the potatoes had been planted, but where every row had been there was plainly visible a thicker and better growth still. When I broke up the ground again 20 years later, and grew other produce, the good effects of the bonedust were seen upon this also. It is not like some manures, whose benefits appear to last for a year only. I once sowed about 3cwts. of bone super. on a little more than an acre of land. I kept the stock off it, and it grew an enormous quantity of grass, which I made into hay; but it seemed to exhaust the land, for the following year it grew very little. With bonedust the good results show for years. Not only is it good for the soil but good for the stock, for they feed with greater relish on the grass grown on bonedusted land, and consequently thrive better. I would therefore recommend sowing 2cwts. (or more if possible) of bonedust to each acre of grass land annually for several years. This, I suppose, could be done for 12s. per acre, or 15s. if drilled or harrowed in. I do not think it is necessary to harrow or drill it in unless it is upon a hillside; then harrow or drill it across the hill, not up and down, or the greater part of it may wash away. On the level parts it would suffice to simply sow it and allow the rain to take it down to the roots, keeping the stock off it until a few showers of rain fell. The beginning of the winter is the best time to apply the manure. The question will naturally be asked, will it pay? I certainly think it will. Twelve shillings or 15s. may seem a lot extra to obtain from an acre each year, but it only means, with an average price of 6d. per gallon, 2½galls. to 30galls. of milk a year extra for each acre, or a trifle over half a pint per day. It would not be advisable to increase the stock to get the extra return for the increased outlay for a few years at least, but to look for it in better condition of the stock and an increase of the yield of milk. As a result of manuring the grasses grow thick without the addition of grass seed. With bonedust, of course, all the benefit will not be visible, neither will it be exhausted in one year, but it will last for many years, and if the quantity is added yearly for several years there will be feed for an increased number of stock. On large farms no doubt the keeping of sheep is of great benefit, but where this is not practicable, and it is desired to continue dairying, the annual dressing of bonedust or some other manure suitable to the locality will be of great help and benefit."

Mr. F. H. Shiedow (Clarendon) instanced a case where 15 years ago farmyard manure had been put on grass land. The result of this dressing was visible to the present day. However, with some of the grazing land in the

district it was almost impossible to apply manure on account of its uneven nature.

Mr. F. DeCaux said the chief cause of the impoverishment of the land in the district was overstocking. While the droppings from the animals added to the fertility of the soil in the summer, in the winter the value of this manure was largely lost, as the rains washed it away.

Mr. S. Smith (Meadows) expressed the view that the land was improved by the addition of leaves shed from the trees. If they burned more of the rubbish in the shape of gum leaves, &c., the potash would nourish the land. There was plenty of grass seed in the soil, all it required was stimulation.

Mr. C. Ricks (Cherry Gardens) stated that in the old country a great deal of attention was paid to the manuring and harrowing of grass lands. He believed that 30 acres of well-cultivated grass land would give a return equal to that from 80 acres worked under the present system.

THANKS TO THE MINISTER.

At this juncture, at the instance of the Secretary of the Meadows Branch (Mr. W. H. Bertram), a vote of thanks was extended to the Minister of Agriculture.

In reply the Minister expressed his surprise at the fact that no one had mentioned the use of lime for the purpose of improving the land in the district. Whilst he was coming along that morning the land near Meadows had appeared to him to be extremely cold. One of the best fertilisers for cold-soils, especially when clay lay underneath, was lime. In so far as the value of animals as manuring factors was concerned it was well known that even in grazing some of the essential elements of fertility were removed from the soil. At the same time stock would not take off anything like the quantity that would be removed in a crop of hay, and, further, would return a certain proportion in the droppings. The aim of the farmer and the dairyman should be not only to maintain the degree of fertility, but also to increase it. Professor Perkins was conducting some exceedingly interesting experiments at Roseworthy, with a view to ascertaining the effects of different quantities of artificial manures upon the pastures. Sheep were weighed into and out of special plots, and the contrast between the carrying capacity of the land heavily manured and that only lightly dressed was very marked. Personally he was convinced that the results of the investigations would be a complete eye-opener to landowners throughout the State and prove to be of much benefit. Every farmer, in a small way, should be an experimentalist. If he were, the advantage to the country would be tremendous, because generally when a tiller of the soil made a discovery of value he was not slow to pass the information on to his neighbor.

AFTERNOON SESSION.**CONTAGIOUS MAMMITIS AND CONTAGIOUS ABORTION.**

In an interesting address on this subject the Veterinary Lecturer (Mr. F. E. Place, M.R.C.V.S., B.V.Sc.) said there were very few farmers who took the trouble to cut up the udder of a cow for the purpose of studying its constitution, and for this reason he mentioned that this portion of the beast was divided into two separate halves by a layer of tissue, which acted simply as a means of support. Each of these halves were again divided into two quarters containing glands, a special form of animal substance required for a special kind of work. The particular function of the udder was to rob the blood of the substances which were needed to make milk for the support of the young primarily, and secondarily to continue the process as long as possible for dairy purposes. The manufacture of the milk was carried on by the cells extracting from the blood that portion they required. This arrangement required a special blood supply. A glance at the milk veins, which would reveal whether they were well developed, would enable one to tell the good yielding cow. Although they were quite correct in judging the cow's capacity for milk production from the condition of what were usually regarded as the milk veins, these were generally channels which were taking from the udder blood that had already been treated there. They were called milk veins, but they were not veins at all, being vessels which took away waste matter. They ran side by side with the veins, and for all practical purposes they might be regarded as such. In order that they might carry away the blood, however, it was necessary that they should have arteries to bring the blood to the udder. From these it was distributed amongst the fine network of arteries which ran alongside the special milk cells. The changes which were effected here were of a totally different nature from those which took place in other parts of the body. If they made analyses of blood and milk they would find that, although the substances in the milk were already existent in the blood, there was a considerable difference in the proportion of the constituents. For instance, in blood soda salts would be found in excess, whereas in the milk potash salts would predominate. It was necessary that these changes should be under the control of the nervous system of the animal, wherein arose the vast differences between the milking qualities of the different beasts. Knowing this, it was a mistake to unduly hurry or excite the cows, and a change of the milker, housing, or feed affected the flow of milk, pointing to the fact that the secretion was under the immediate control of special nerves. In order that the blood supply might come into the udder, and be treated in this way, it was necessary to provide for a complete system of drainage. Part of this was carried out by the milk veins which were visible and part by the lymphatics. These were the receiving junction of the waste products of the blood, and in the udder they were placed high up in the hind quarters. All the waste that was not fit to

go back into circulation was dealt with by these. The constituency of the milk could be immediately modified by the food that was given; but the food not only affected the quality and the quantity of the milk but the capacity of the milk gland itself, and thus the working power of the gland depended on the nature of the food that was given. It should also be remembered that when there was a delicate organ like the udder to deal with it must be treated carefully. At the first calving of the heifer, when the blood circulation was being readjusted, the udder would probably be the weakest point of the whole system. Therefore the animal should not be subjected to unnecessary violence, changes of temperature, changes of feed, &c. Every damage that was done to the udder should not be called inflammation of the udder. Many persons mistook ordinary congestion as mammitis. The highly-strung nervous young heifer coming into calf desired to send as full a flush of milk into the udder to feed the calf as was possible, and so materially affected the changes which were going on inside that portion of her body. The udder swelled and filled out for the purpose, and perhaps the dairyman gave her more food. Then it would be noticed that the beast got fidgety and the udder became still larger. The teats stood out and were painful, and there was a decided swelling running along from the front of the udder to the belly, and down to the hind legs as well. Under natural conditions the calf would relieve the trouble by sucking the teats. The application of lard or butter was much better than the rubbing in of some strong stimulating liniment. Although this condition was relieved by simple remedies there were cases that presented greater difficulties. The pain was so great that the animal showed signs of it. These were real cases of udder ills. The milk cells had to go on working, and the network that supported them became torn and painful, and the whole condition foreshadowed the loss of the milk in one or more quarters. In this part of the world occasionally diseases formed in the udder, and there was a dark purple staining of the skin. This occurred through neglect in watching the animal. In the great majority of the cases, if the congestion stage had been carefully treated there would have been no trouble with this. Under the microscope the congested state of the udder described above and contagious mammitis could be easily distinguished. The latter disease was co-existent with the presence of certain germs which got into the udder by various means. They got in with the blood that was flowing into the udder, and multiplied in the drains by which the waste was carried away; but more commonly they obtained access through the opening of the teats, and when once in their numbers grew rapidly. The trouble was transmitted by the cows lying down on affected areas, or through the hands of the milker. There was a very simple remedy, viz., warm soapsuds well rubbed in. The milk would perhaps be somewhat thick, and it would be found that it was acid, the result of the growth of these germs, and the amount of soda in the soap was sufficient to counteract the

acidity of the udder, and so render it an unfavorable ground for these germs to grow in. Therefore, if there were any suspicion of anything of this nature going through the milking herd it would pay to thoroughly cleanse the udder with soapsuds. If a more acute form had to be dealt with a solution of boracic acid could be squirted into the teat. About three-quarters of an ounce dissolved in a pint of warm water and 4ozs. to 6ozs. administered to each quarter daily for a few days and then at longer intervals for a week or two should be effective. This would render the germs weak and sickly. When there was any suspicion of the existence of the disease in the herd the suspected animals should be milked at the last.

CONTAGIOUS ABORTION.

The lecturer drew attention to the fact that about 28 years ago so much difficulty was occasioned by this disease that strenuous efforts were made to discover the cause. Seven or eight years ago the germ responsible for the trouble was recognised, and it was now known that the membranes of the cow's womb and vagina were a favorite growing ground of this particular germ. The result of its presence was that cows would throw their calves generally between the third and seventh month, and although they returned to the bull they rarely became impregnated. These were the only symptoms one was likely to notice in the case of an outbreak of contagious abortion. The first step necessary in treatment was the thorough destruction of the aborted calf. A curious feature in this regard was that where an aborted calf was left exposed all the pregnant cows exhibited an interest in it, with the result that they were very likely to get germs into their systems. Some authorities contended that the chief means of infection was with the feed. A strong solution of perchloride of mercury or kerosine oil should be thrown over the beast, and it should be burnt. Then the place of burial should be well dug over, as otherwise the cows remained on the edge of the burnt ground and ran the risk of infecting themselves. If the disease were well established, and it became necessary to take some active measures to stop it, a packet of tabloids of perchloride of mercury and about 3ft. of $\frac{1}{2}$ in. rubber tubing, together with a glass or enamel funnel, should be procured. It was useless to put the solution into any metal receptacle. One of the tabloids should be dissolved in an ordinary wine or whisky bottle filled with water. A few inches of the tube should be inserted into the bearing of the cow and the mixture poured into the funnel from the height of the balance of the tube, thus disinfecting the vagina of the animals. Where the calf had been slipped it would be often found that there was a persistent discharge from the cow. It was then necessary to syringe the animal's teats daily for three days, and then once a week for three weeks. A bull should be kept for the service of those cows that were affected, and after service the sheath of the beast should be syringed. An authority in the old country stated that when an animal

slipped its calf it would be immune to further infection. It would generally be found, however, that such cows would not be got in calf. It was possible to tell, by subjecting the blood to certain processes, whether the germ of abortion was in the system. As a practical means of preventing the spread of the disease in a district such as this he recommended the destruction of the aborted calves with perchloride of mercury.

The address was followed by an interesting discussion, in which a large number of delegates took part. Questions relating to the subject matter of the lecture, as well as to various points of interest to stockowners, being asked and satisfactorily explained.

THE BUSH FIRES ACT.

Mr. T. Jacobs (Cherry Gardens) submitted the following resolution:—“That landholders in certain districts be allowed to burn scrub, &c., in November, both by night and day, and in February, March, and April by night in addition to the daytime, as already allowed.” In introducing the motion he said that the provisions of the Bush Fires Act, in so far as they applied to the hills and a good many other districts, were most unsatisfactory. Landholders were not permitted to burn during November, and it was very seldom, in this district at least, that burning could not be carried out with perfect safety during that month. He blamed the Act in a large measure for the extent of the damage which had been done last summer by fires, for had landholders been able to each burn breaks at their discretion the fires would have been confined to limited areas. The Act permitted the burning of scrub at any time, provided an area of half a chain width was cleared around the scrub to be burnt. This was by no means an effective break. Another point was that fires were not to be lit at night. He contended that it was much easier to control a fire during the night than was the case in daytime.

Seconded by Mr. J. Stone (Meadows).

Mr. G. G. Nicholls (Secretary Advisory Board) drew attention to the fact that Congress had passed a resolution as follows on the subject:—“That district councils be empowered to fix the dates as well as hours for burning stubble and scrub in their respective districts.”

Mr. A. L. Morphett (Clarendon) moved as an amendment that the resolution of the Annual Congress be supported by the Conference of the Hills Branches.

Mr. W. Pearson (Mount Barker) seconded the amendment, which was carried.

NEXT CONFERENCE.

Delegates from the Clarendon, Longwood, Mount Barker, and Morphett Vale Branches expressed a desire that the next Conference should be held in their respective towns. It was eventually decided to accept the invitation of the Mount Barker Branch.

CONSERVATION OF WATER.

This subject was dealt with in a paper by Mr. Brooks, which he had previously read at a meeting of the Clarendon Branch, and which is to be found on page 378 of the October, 1912, issue.

The subject was discussed at length by delegates.

Mr. W. Pearson (Mount Barker) had constructed a reservoir in the hills. He commenced with the idea of raising the embankment to a height of about 18ft. When it reached 13ft. he found that there was insufficient width to allow of the scoop being used on top. The width of the bottom was 51ft. He placed a 3in. pipe underneath the embankment at the lowest level of the dam, and by means of this was able to completely empty it by gravitation.

THE ADVISORY BOARD AND BRANCHES.

Mr. G. R. Laffer (Advisory Board), in expressing his pleasure at being present at the Conference, stated that the large attendance spoke well for the interest taken in the Bureau by agriculturists. At present the Bureau was stronger than it had ever been, and the Board had been strengthened by the addition to its membership of Professor Lowrie, and Messrs. F. Coleman, of Saddleworth, and C. E. Birks, of Wandearah. That body was always ready to give due consideration and attention to matters which Branches brought before it; but he urged them to thoroughly weigh all the evidence before making a recommendation to the Board. The Secretary to the Board (Mr. G. G. Nicholls) had done a great deal since his appointment in furthering the interests of the Bureau, and he paid a tribute to his energy and enterprise.

IRRIGATION IN THE HILLS.

Mr. C. Ricks (Cherry Gardens) read an interesting and instructive paper on this subject, the text of which will be found on page 858 of the March, 1912, issue.

EVENING SESSION.

PROFITABLE MANAGEMENT OF THE DAIRY HERD.

This was the subject of an interesting address delivered before a large gathering by Mr. P. H. Suter, the Dairy Expert. He pointed out that dairying was one of the most profitable branches of mixed farming, and that the housewife who milked cows and kept poultry was able to provide the necessities for the house, keep the family well clothed, and still have enough left over for the purchase of seed wheat for the farm. In some districts there was too much uncertainty about the climatic conditions, and in those cases the sensible farmer would not depend altogether upon his cereal returns.

The advantage of dairying lay chiefly in the fact that it admitted of immediate returns. In New South Wales, Victoria, New Zealand, and Denmark the industry had proved to be the salvation of the people. He knew of many instances where farmers would certainly have gone through

the Insolvency Court had they not diverted their attention to cows. Unfortunately many people had become too prosperous and contented, and, consequently, they depised the work essential in the management of a dairy. He quoted Denmark as an illustration of sound dairy practice. That country once was in sore straits, but by wise legislation and co-operation in dairying, it had become one of the richest in Europe. Although only one thirty-third the size of Victoria its dairying industry to-day was worth £20,000,000. The Danish dairyman had brought his methods of management up to a high level by keeping careful records of the milk and butter yields of each cow. Thus, those cows which were unprofitable were eliminated from the herd, with a consequent increase of profit to the dairyman. One successful dairy farmer had said just as the enrichment of the soil gave the best conditions for the seed, so a well-grounded humanistic training provided the surest basis for a good business capacity. Business management was lacking to a large extent among South Australians, especially in respect to the testing of dairy cows. He had always strongly recommended the more general use of the scales and the Babcock tester on the farm. He was pleased to report that a number of farmers were now employing them. Testing associations he regarded as valuable, but such organisations would not prove successful in the central State, except in isolated areas, principally because the rural population depended more on mixed farming. The settlers were more scattered than in the dairying districts in the eastern States, and held comparatively large areas. He advised that a few farmers in each district should buy a testing outfit between them, and he would give them thorough instruction how to perform the work. Already that course had been adopted in some localities. The man who trusted to guesswork in appraising the productive value of each cow was likely to allow a serious leakage in his annual returns. Proof of this was supplied in the case of a farmer who had singled out the best six cows in a herd of 40, and had then tested the whole herd. At the conclusion of the lactation period he had found that his chosen cows stood in the following order of merit:—First, the fifth cow on the picked list; second, a cow not on the list; third, the fourth of the selected animals; fourth, a cow not on the list; fifth, the beast first on the list; sixth, the animal which he had placed second on the list. That demonstrated that guesswork might be very misleading. He considered that fully 40 per cent. of the cows now maintained on the various farms were "boarders." The unprofitable animals should be passed off to the butcher, and not transferred to some unsuspecting brother. He cautioned dairymen that it was unwise to condemn a cow on a test covering only its first lactation period, particularly if she had come from a good milk-yielding family. Another point to be remembered was that an adequate and judicious food ration was necessary before they could properly pass judgment upon a cow. He had in mind a cow sold by a so-called dairyman for a few shillings, because she was regarded as a failure. Her new owner

fed her well, with the result that she not only showed a record of more than 26lbs. of butter a week, but won a handsome prize.

CHOOSING A BULL.

They had always to bear in mind that the milk went down the throat. An approved bull was an essential. Unfortunately there were some dairymen who would use any animal to save expense. The practice of selecting a bull calf from a scrub-bred herd had nothing to recommend it. The bull should be chosen from a pedigreed deep milking strain, with a view to breeding for improved milk and butter capacity. Careful mating of purebred sires with common cows would enable them to grade up and bring about a decided increase in average production. He discouraged the practice of keeping heifers whose mothers had been failures at the pail. Assuming that a farmer owned a herd of 30 cows, it was safe to reckon upon 15 heifers a year. If these were the progeny of a wisely-selected bull their value would be nearly doubled. He had known of a herd's production having been increased in that way to the extent of 4lbs. daily per cow. Allowing that the period of lactation extended over 270 days, the increase indicated meant an improvement of 1,080lbs. a cow. In six years the enhanced production per cow, with the milk valued at 6d. a gallon, would amount to £16 4s.

For an hour and a half at the conclusion of his address Mr. Suter was kept busily engaged in answering questions. He emphasized the importance of cleanliness in the dairy, the necessity of proper feeding, and the value of judicious breeding.

GENERAL FARM MANAGEMENT.

An interesting paper on this subject was read by Mr. N. Cobbledick (Uraidla), in the course of which he pointed out that the homestead should be made as bright and attractive as possible, and in addition should be kept in good condition and repair by the landholder. A good substantial fence should surround the property, and it was advisable in all cases to keep good young stock. It was hard to estimate the value of the cow on the farm, as in addition to the supply of milk and cream there was the profit derived from feeding the surplus to pigs. These latter animals should be supplied with warm well-drained styres, which should be cleaned out at regular intervals. A fair number of good hens regularly supplied with shell grit, clean water, and an abundance of green feed should be kept in good clean yards. He advised all farmers to leave a belt of timber on their property for the purpose of shelter, and also to provide a supply of firewood for the home. Cropping should be done systematically, and where necessary drains should be put down to take off the floodwater. The irrigation of a small plot would enable the landholder to grow summer crops for the stock, and strongly recommended the growing of field peas as a change crop. No homestead should be without a fruit orchard, to which careful attention should be given.

ARSENATE OF LEAD ANALYSES.

The following nine samples of Arsenate of Lead, procurable from Adelaide dealers, have been analysed by the Government Analyst (Mr. W. A. Hargreaves, M.A.), with the results detailed below :—

No.	Name.	Approximate Weight of Contents of Package.	Weight of Water in Package.		Dry Weight of Arsenate of Lead.	
		Ozs.	Ozs.	Grs.	Ozs.	Grs.
1	"Electro"	17½	6	170	10	376
2	"Electro Bordo Lead"	16	9	315	6	122
3	"Our Jack"	16½	0	44	16	284
4	"Electro"	14½	0	24	14	304
5	Merck's	16½	0	27	16	82
6	Swift's	18½	9	109	10	328
7	"Bluebell"	15½	5	152	10	176
8	"Hemingway's"	32	17	185	14	252
9	"Nicholl's"	15½	5	174	9	372

ANALYSES OF SAMPLES ON THE DRY BASIS.

No	Oxide of Lead (PbO).	Arsenic Pentoxide. (As ₂ O ₅).	Water Soluble Arsenic Pentoxide.	Water Soluble Lead Oxide (PbO).	Copper Oxide (CuO).
	Per cent.	Per cent.	Per cent.	Per cent.	Per cent.
1	62.48	32.39	0.22	Trace	—
2	46.55	23.79	0.10	"	7.10
3	62.37	27.77	0.23	"	—
4	65.34	32.29	0.17	"	—
5	72.14	22.38	0.06	3.86	—

7	66.94	21.15	0.08	"	—
8	62.20	33.05	0.88	"	—
9	62.22	32.17	0.26	"	—

N.B.—No. 2 is a mixture of arsenate of lead and Bordeaux paste. Arsenate of lead should contain not less than 25 per cent of arsenic pentoxide (As₂O₅) combined with lead, and not less than 1 per cent of water soluble arsenic compounds, calculated as arsenic pentoxide, both calculated on the dry basis.

ADVISORY BOARD OF AGRICULTURE.

Dates of Meetings—

November 13th, December 11th.

THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the department for fuller particulars concerning the work of this institution.

REPORTS OF BUREAU MEETINGS.

Edited by GEORGE G. NICHOLLS, Secretary Advisory Board of Agriculture.

UPPER-NORTH DISTRICT.

(PETERSBURG AND NORTHWARD)

Amyton, September 26.

(Average annual rainfall, 11½ in.)

PRESENT.—Messesrs. T. O'Donoghue (chair), S. Thomas, J. J. Cormack, T. Griffin, A. J. Phillis, T. Ward, R. Brown, D. P. Aitken, H. K. Gum, A. Wallace, A. Crisp (Hon. Sec.).

LUCERNE-GROWING.—Mr. H. K. Gum read the following paper on this subject:—
“Owing to the very uncertain rainfall in this district it is necessary to irrigate in order to grow lucerne successfully. After a test extending over a period of six or seven years, I consider that the flooded lands in this district are very suitable for lucerne-growing. The best seed obtainable should be procured. I prefer the Hunter River variety, as it is a rapid grower and thrives well. It can be grown with wheat on well-worked fallow, but great care must be exercised not to bury the seed too deeply. One paddock of lucerne, which has done remarkably well, was only trodden in by sheep. The wheat had been up for some considerable time, and immediately after the lucerne was sown a flock of sheep were turned on to it and kept there until the wheat was fed off short. The sheep were turned on about the middle of July, and by hay-making time there was an excellent crop of lucerne with the wheat. The majority of it was then cut for hay, which had the effect of making the lucerne stool out and grow much thicker. This took place six years ago, and the lucerne has done well through the summer and winter up to the present time without having been once cultivated. During each of the past two summers it has gone three or four months without any flood waters running over it, but it has continued to grow well without apparently suffering for want of moisture. Previously to that time, however, it received several floodings throughout the summer months of each year. This paddock is sufficient proof that lucerne can be successfully grown on overflow country, even with the moderate average rainfall of about 12 in. Once lucerne is established a long dry summer has very little effect upon the crop. As soon as a good rain falls it commences to grow. The sample tabled was taken from a paddock that had a fire through it in April of last year. Later on it was fallowed, and has been scarified and harrowed several times since, with the result that the lucerne, which was sown about four years ago, has made this remarkable growth in 10 weeks, *i.e.*, since seeding was finished. This proves that ploughing or cultivating has no detrimental effect upon lucerne, but is rather inclined to make it grow much better. The great advantage of lucerne is that it is at its best when all other feed is dry, *i.e.*, during the summer months. Six or seven pounds to the acre is sufficient seed to sow, as it will naturally get thicker each year. If it is too thick it becomes root bound and will not thrive. Should this occur it is advisable to cultivate it. This will break some of the roots and prove very beneficial to the crop. It is possible for all who have any land that is occasionally flooded to secure similar results. There is nothing that will give better returns as feed than lucerne. I would advise everyone to give it a trial, but care must be taken that the seed is not buried too deeply. Once a lucerne plot is established it is a most profitable undertaking, and there is very little work attached to it.” A good discussion followed the reading of the paper.

Coomooroo, August 29.

(Average annual rainfall, 12in.)

PRESENT.—Messrs. Berryman. (chair), W. Robertson H. Fisher, A. Cooke, A. Brice, F. Gregory, E. and R. Brice, C. and C. Phillis, R. G. Polden (Acting Sec.), and one visitor.

LUCERNE.—Mr. H. E. Fisher read a paper on this subject. While lucerne was most successfully grown where it could be irrigated, he said, it could be grown without irrigation on very many farms. On nearly every farm suitable plots of ground were available for an experiment with this fodder. In the North it was advisable to select a piece of low-lying ground on to which the floodwaters could be turned. Good crops had been grown in this way in the North. The method of sowing he advocated was to put the seed in with the wheat, which protected the young plant. Mr. Robertson had not been successful with lucerne sown with wheat. In his experience the sowing had to be done too early for the lucerne. Members were of the opinion that 50 acres of good lucerne ground, when fully yielding, would provide a living for a man who carried on dairying and fattening stock.

FALLOWING.—Mr. Robertson drew attention to the fact that many crops in the district were being partially choked by weeds, the seeds of which had not germinated in the fallows till after seeding. The difficulty was that the oats did not grow in time for the farmer to kill them by cultivation. He urged shallow ploughing with skimming or light cultivation late in July to get the fallows clean. Mr. R. Brice said that oats would grow more quickly after the cultivator than they would after the plough. The trouble was that in these areas farmers could not keep enough cattle through the summer months to keep down the weeds on the fallow in the winter and spring. Mr. A. Cooke considered that fallowing should be finished in July and afterwards worked down fairly fine. He would sow whenever possible after rains. Members generally agreed that shallow ploughing to get the oats up as soon as possible was the main factor in cleaning fallow ground.

Coomooroo, September 23.

(Average annual rainfall, 12in.)

PRESENT.—Messrs. E. Berryman (chair), Brown, Robertson, E. and R. Brice, Phillis, Cooke, A. C. Brice (Acting Hon. Sec.), and two visitors.

FARM IMPLEMENTS AND MACHINERY.—Mr. A. C. Brice read a paper dealing with the care of implements and machinery. The life of an implement, he said, must be reckoned by the acreage worked rather than by the length of time in use. Implements and machines were costly, and if worn out by bad treatment and carelessness were of little value for any other purpose. In purchasing, the farmer should be sure that his implements were strong enough for the soil to be worked and for the team strength to be used. The farmer's desire for a light draught implement led the manufacturer to make one that was not durable. He would prefer an implement without a seat upon it, so that instead of allowing for a man's weight the implement itself would be heavier and stronger. Upon examination of a new machine or implement any part causing needless friction should at once be attended to, and as the implement became older a watch should be kept for wearing parts which could be packed or repaired in time to save costly renewals and breakdowns at an awkward time. Thorough oiling was necessary to prevent the wasteful wearing of parts. When not in use all implements and machines should be stored in a good shed. The best protection for woodwork was boiled oil, and two coats a year would preserve the appearance as well as lengthen the life of the implement. The oil should be put on when the wood was perfectly dry. He had recently seen two wagons, one built three years ago, while the other had been in use for nearly 40 years. To the ordinary observer the old wagon, which had been properly cared for, would certainly appear to be the more recently built. He made a practice of leaving the oil on the bearings while the implement or machine was out of use, and cleaning it off just before it was called into service again. This would prevent the bearings from rusting. Some oils would cake if used on a fast-moving bearing, while others would run to waste on the parts that revolved more slowly. A drum of machine oil, another for cultivating implements, and one of boiled oil used judiciously on a farm plant would save a lot of money every year.

Craddock, September 28.

(Average annual rainfall, 10½ in.)

PRESENT.—Messrs. J. Patterson (chair), Graham, Neylon, Harris, Jago, Clarke, Glasson, Gillick, Adams, P. Neylon, J. Smyth (Hon. Sec.).

DRY FARMING.—In a discussion on this subject, Mr. A. Clarke said it was necessary to rid the land of weeds in order to grow wheat. In the earlier days there was very little grass with which to contend. He did not think working the land more than in the ordinary way was required, as in former years good crops were grown with the ordinary ploughing and harrowing. Mr. P. Neylon considered that if the farmers in the wet districts were to cultivate as was done here they would not grow payable crops, with which opinion Mr. Jago agreed. The Secretary thought too much work could not be put into the land here at the right time. As an instance, some farmers in a 20 in. rainfall fallowed the land for two seasons and cultivated between in order to keep the weeds under. With this system of cultivation 50 bush. to the acre had been harvested, whereas on farms where the land had only been fallowed once 20 odd bushels to the acre were returned. This gave a good margin, considering the extra labor entailed and the idleness of the land. Mr. Graham put in a crop of wheat last year in the ordinary way, i.e., fallowed in August and broadcasted the seed and harrowed it twice, and reaped more wheat than was secured from his neighbor's adjoining paddock, who tilled his land under the dry farming system. Some years ago he worked his cultivators on the headlands, going to and fro to work, until it became a dust-hole, and when the rain came it caked. The return from it was not so good as where the land was not worked so much. Tilling and manuring were of no use without moisture.

Hookina, September 24.

PRESENT.—Messrs. D. Madigan (chair), J. Henschke, J. Carn, P. and T. Kelly, B. and P. Murphy, S. Stone (Hon. Sec.), and three visitors.

PREPARATION OF THE WOOL CLIP.—Mr. Henschke addressed the meeting briefly on the subject of preparing wool for market. He always classed bellies, pieces, and locks separately, and where necessary made two classes of each. Heavy, greasy fleeces should be classed independently of lighter wool, as the selling value was affected if they were mixed. It was inadvisable to make the bales too heavy. Mr. T. Kelly said that in Ireland sheep were always washed before shearing. This practice could, in some cases, be followed here.

Hookin, October 26.

PRESENT.—Messrs. D. Madigan (chair), L. Woods, J. and A. Henschke, J. Carn, P. and T. Kelly, B. Murphy, S. Stone (Hon. Sec.), and two visitors.

HAYMAKING.—Mr. S. Stone read the following paper on this subject:—When sowing for hay, it is advisable to sow hay varieties. A wheat that produces an abundance of flag is preferable to a clean strawed sample. It is also better to sow an early wheat, as this allows more time for stacking before later wheats are ready for the stripper. Much of the quality of hay is lost through not cutting it at the right time. The straw should not be too dry, especially where it has to be fed long, as the stock will eat the heads and leave the hard stem. It should not be cut too green, as it then becomes light and marshy. The binder is the best means of handling the hay crop, as it is the least wasteful. It also makes it possible to cart and stack in windy weather, which often means a great saving in time. It is advisable to leave the sheaves a day or two after they have been cut. Where they are still fairly green it is safest not to put too many into a stook, 10 or 12 being sufficient. When building into a stack, keep the outside sheaves fairly level. This lessens the tendency to slip either way and makes building easier." Mr. B. Murphy advised harrowing the ground to be cut for hay, and preferred Bluey and Fill-the-bag as hay wheats. Mr. A. Henschke thought Purple Straw the best variety. Mr. Kelly preferred loose hay to sheaves for feeding long, as horses could not eat off the heads so easily. Mr. Madigan said King's Early was a good wheat for hay, and thought the binder had many advantages over the mower.

Orroroo, October 25.

(Average annual rainfall, 13½ in.)

PRESENT.—Messrs. M. W. Forrester (chair), H. J. Cottrell, R. Shillabeer, S. S. Hook, T. H. P. Tapscott, A. L. Brice (Hon. Sec.), and two visitors.

FAT LAMB RAISING.—The Hon. Secretary contributed the following paper:—"I wish to bring before your notice the fact that it is possible, with very little trouble, to add considerably to your income by keeping a few ewes and raising lambs suitable for export. We will take it for granted that Merino ewes are kept, as they are always obtainable and can be relied on to produce a heavy and profitable fleece. Then comes the question, 'What breed of ram are we to use to get the best results?' In this State there are six breeds that are well known, each having a section of admirers. The Southdown is a smaller but similar sheep to the Shropshire, the lamb being an ideal shape, and growing slightly faster than the Shropshire lamb. In my opinion the Dorset Horn is a better ram in this respect than either of the two previously mentioned, as the lambs mature sooner, and can be placed on the market while the prices are high. Dorset rams can be put with the ewes a fortnight later than Merino rams, and the lambs are ready for market before the Merinos; this also applies to a lesser extent to the Shropshire and Southdown. In the matter of tailing, I am in favor of using the searing-iron in preference to the knife. The iron does not cause the lambs to bleed, as they do when the knife is used, and they are therefore less apt to receive a check in their growth, which is important when it is necessary to have them ready to send away as early as possible. Lambs should be tailed when about three weeks old. Older lambs feel the effects more than the smaller ones. I have heard it stated that the stump of the tail does not heal as quickly when the searing-iron is used. I have watched carefully, but could not detect any difference. It is a good plan to change the sheep from paddock to paddock fairly often. It is more advantageous to have a number of small paddocks than to have one large one of similar acreage. Sheep should always be allowed access to water, from wells in preference to dams, and if the water is slightly brackish it is better for them than rain water. If a farmer has 200 well-woolled Merino ewes, and raises lambs for export, I do not see any reason why the ewes should not produce an average of £1 each annually, including the value of the lamb and the wool. This year, on August 17th, I weighed five lambs, aggregating 344½ lbs.; on September 5th they were again weighed, and this time they totalled 411½ lbs., a gain of 67 lbs., or an average of 13½ lbs. in 19 days. The best of these lambs weighed 76 lbs. on August 17th. It was shorn on September 16th and weighed again on September 19th; it then reached 100½ lbs., a gain of 24½ lbs., and allowing 4 lbs. for weight of wool to be added, making a gain of 28½ lbs. in 33 days. This will show how rapidly a lamb can mature under favorable conditions. I have made no comment on the Leicester, Lincoln, or Romney Marsh rams, as I have had very little experience with them, but the first two breeds appear to be suitable for lamb production, judging by the number who advocate their claims. In conclusion, I hope this paper may be the means of inducing you to seriously consider the advisableness of raising a few suitable export lambs, even if only half a truckload."

Quorn, October 26.

(Average annual rainfall, 13½ in.)

PRESENT.—Messrs. R. Thompson (chair), Noll, Finley, McColl, Bury, Schulze, Cook, Brewster, and Patten (Hon. Sec.).

SELECTION OF SEED.—In a paper on this subject, Mr. McColl drew attention to the importance of carefully selecting wheat for seed. It was well known that wheat deteriorated if care were not taken with the seed, and it was also known that the yielding quality could be improved by selection. Farmers should do something for themselves in this direction, and he recommended them to select hardy and drought-resisting wheats for the purpose of testing and improving the yields. As a general rule, there was insufficient experimenting done by the farmers of South Australia. Members generally agreed with the views expressed by the writer, and the Chairman stated that if they sowed inferior seed they could not expect to reap first-class wheat. Mr. McColl, in reply to questions, said it was advisable to select the best heads from the plots sown, and sow these again at the following seeding.

Willowie, September 30.

PRESENT.—Messrs. T. Hawke (chair), E. S. Bristow, S. C. Greig, W. B. Bull, A. R. Wilkin, F. Richter, A. W. Howard, L. Hughes, E. J. Kentish, S. Tucker, A. Gray, D. McCallum, W. P. Foulis (Hon. Sec.), and two visitors.

REVIEW OF CONGRESS.—At the conclusion of the report given by Mr. W. P. Foulis, who was one of the delegates, some discussion took place concerning barley-growing for this district. Several members had known barley to be successfully grown in this locality, but the trouble was it became a nuisance in the wheat crops. Members were divided in opinion as to whether barley would stand the drought better than wheat. Mr. Howard mentioned in respect to the feeding value of barley that it tended to fatten stock, while oats helped more in the formation of muscle. Mr. McCallum commented upon his visit to the Roseworthy Agricultural College and Experimental Farm. He considered that the Government experimental farms were of very great benefit to the State, as they were able to carry out research work, which would be too expensive for private individuals to undertake.

Willowie, October 22.

PRESENT.—Messrs. B. E. Schmidt (chair), S. C. Greig, A. W. Howard, E. S. Bristow, A. Gray, W. B. and S. Bull, F. Richter, L. Hughes, W. P. Foulis (Hon. Sec.).

HAYMAKING.—The following paper was read by Mr. S. C. Greig:—"The quality of hay which the farmer feeds to his stock has a great deal to do with the work that they are able to perform. Marshall's Hybrid and King's Early wheats are good varieties for hay. The seed should be free from smut, and it is not advisable to pickle it. Land intended for the growth of hay should be immediately rolled after seeding. If this is done, not only is the return per acre higher but the gathering of the crop is much easier on the binder. When it is the intention of the farmer to cut roads around the wheat paddock, these also should be rolled as soon as the seed is drilled in. The crop could then be cut short, and after ploughing a few rounds an excellent firebreak is made. Before taking the binder out each season the bearings should be kerosined, and care should be taken to see that they are all taking the oil freely. The hay should be cut fairly green, especially if it contains a percentage of oats. Where a clean wheat crop is to be cut, it should be left until it has good grain, for it will then be found to turn out heavier. Stooking should be carried out as soon after cutting as is possible, as the sheaves are then more easily handled and the stooks will better stand rough weather. Where hay is left lying during showery weather, in all probability it will be found slightly tainted when dry enough to stook. If the hay is extra green the stooks should be only three sheaves wide, but in the majority of cases the four-sheaf stook will be found most satisfactory. While the stook can be made to any length, it is necessary to keep the sheaves upright. The hay will then stand well, dry fast, and be easy to cart. Great care should be taken that the hay is perfectly dry before stacking. Even the slightest toughness in the centre of the sheaf renders it unfit to be put into the stack. Two weeks after cutting will generally be found soon enough for carting, but much depends on the weather and the class of hay. The most suitable conveyance for carting is the trolley, but where wagons are used a 10ft. by 16ft. frame with end hurdles 6ft. high, straight up, should be used. The frame with sloping hurdles means that too much high pitching has to be done and there is more danger of their breaking. Where the stack is a chain or more long the width should be not less than 7yds., and round corners are always preferable. Old mallee posts or logs make a good floor for the stack. The correct method of building is to back up with the butts out, placing the butt of the second round nearly out to the strings on the outside round, and so on until the centre is filled up. Building in this way makes the stack firm to stand on. When it is being taken down little damage will be done by fowls if a cut is left open, as the heads of the sheaves are nearly all covered. The heart of the stack should be kept well up, especially when nearing the top. At all heights the ends of stacks should be higher than the middle, as they settle out and go down later on. If they are not kept higher at the edges whilst being built, there is a likelihood of their slipping out. The stack should be wider at the eaves than at the bottom, in order that rain may drip clear. When roofing, it is advisable to put the butts out. The roof should consist of a good coat of Gluyas straw straightened out and carefully packed, then covered with wire netting. The straw should be mowed and handled in cool damp weather, as after it is broken down with the chain or with the harrows it will not run the water off so freely. The weights for holding the netting on the roofs should not be too heavy, as they will in all probability cause the roof to be uneven. Stacks as a general rule should

be built north and south, as when they are placed in the other direction little sun shines on the south side, and there is a tendency for the wheat to germinate in the winter months." In discussing the subject, Mr. Schmidt expressed the view that stacks of about 5yds. wide were most suitable, as there was less danger of the hay being damaged. The centre of the stack should be kept 2ft. 6in. higher than the edges: the butts should be placed out when roofing, as the heads of sheaves rotted very quickly and damaged hay was the result. Straw for covering stacks should be cut with the mower, and straightened out when being placed in position. Mr. Hughes had satisfactorily thatched a stack with sheaves cut with the binder. Mr. Gray did not believe in leaving the crop until the grain was firming, but preferred cutting it just after the bloom had fallen off. At this stage there was more sugar in the hay, and the stock did better on it. He preferred the narrow stacks, as there was less danger of their taking in water. Mr. Howard suggested that sheds with iron roofs were an advantage where hay was grown extensively, as the iron would be found to last for a considerable time and it provided excellent protection. Mr. Bristow thought more care should be taken in stack building, and he advocated the round end, as stacks built in this shape were easier to roof and were not so liable to slip. Mr. S. C. Greig in reply, gave his opinion that horses thrived better on hay cut when the grain had slightly firmed.

CORRECTION.—A paper printed under the heading of "Fencing" in the October issue of the *Journal*, which was attributed to Mr. E. J. Kentish, was written and read by Mr. E. S. Bristow, to whom it should have been credited.—[Ed.]

Wirrabara, September 26.

(Average annual rainfall, 30in.)

PRESENT.—Messesrs. E. J. Stevens (chair), W. H. Stevens, W. Marnier, C. Hollett, P. Lawson, P. H. Hockridge, R. L. Watson, J. Kendrick, A. E. Stott, J. F. Pitman, C. F. H. Borgas, H. Lawson, C. H. Curnow, P. J. Curnow, E. Hollett, J. Hollett, A. R. Woodlands (Hon. Sec.), and one visitor.

POULTRY.—Mr. W. H. Stevens read a paper on this subject. The best laying breeds, he said, were the White and Brown Leghorns: the Golden and Silver Wyandotte and Black Orpington (which was also a good table bird) were considered about the best for farm requirements. The best table birds were Plymouth Rock, Buff and White Orpingtons, Minorcas, Dorkings, and Brown and White Brahma. The most desirable time for hatching chickens was about the end of October or in early November, and iron houses were advisable, as less trouble was then experienced with tick. A good preventive measure for this pest was scalding the roosts and woodwork of the houses with a solution of 10 parts soap-suds and one part kerosine. His recommendation for the farmer was to cross a laying strain with table birds, the progeny being a suitable farm fowl. In the discussion which followed, members generally favored the White Leghorn: the Brown Leghorn being regarded as a good utility bird. The Plymouth Rock was recommended as a brooder, and a good all-round bird was the result of a cross between White Leghorns and Black Orpingtons.

MIDDLE-NORTH DISTRICT.

(PETERSBURG TO FARRELL'S FLAT.)

Beetaloo Valley, September 28.

PRESENT.—Messesrs. A. H. Jacobie (chair), Burton, Bartrum, Ryan, Curtin, Woolford, C. Cox, F. Bartrum, (Hon. Sec.) and two visitors.

VARIETIES OF WHEAT FOR DISTRICT.—Mr. A. Woolford read a paper on this subject, in which he stated that his experiments had shown that it was necessary to work the land to a fine tilth for success in wheat-growing. The soil must be studied in order to ascertain its capability to grow different varieties of wheats. Federation did well on most soils, but gave the best results on red sandy soil, not too wet. For the wet sandy soil and lime-

stone patches of this district he found that Yandilla King and Steinwedel did best. They kept a good color and were not particularly subject to takeall. Steinwedel should be sown at the rate of about $1\frac{1}{2}$ bush. to the acre, as it did not stool so well as some varieties. For this district early wheats were most satisfactory, and Golden Drop was the best of the early wheats. It grew quickly and matured about three weeks earlier than most other varieties. It yielded well and made good hay, but if sown very early was apt to go down. Comeback did very well, but Comeback No. 6 was better, as it did not shake out so badly. Carmichael's Eclipse was a good wheat to sow late. It stooled and grew very well. King's Early did not stool very well, but being a quick grower was a good variety to sow on dirty land. Baroota Wonder was a good variety to sow in a dry year, but it was very susceptible to red rust. The land in the district varied so much that it was necessary to study the nature of the soil for the wheats. He believed in harrowing after the drill— $1\frac{1}{2}$ in. was deep enough. In the discussion which followed members generally considered that Federation was subject to more diseases than other varieties. It was agreed that it was not as good a variety as when first introduced.

Gladstone, October 26.

PRESENT.—Messrs. R. Lines (chair), J. H. Sargent, Brayley, Hollitt, Sampson, T. Mutter, F. Mutter, Peters, Odgers, G. Fisher, Sando, Anderson, T. Brown, Aughey, Blesing, Masters, O. P. Lines, Eley, J. Fisher, J. Page, R. Coe, A. E. Dinning (Hon. Sec.), and one visitor.

CARE OF HORSES.—In an interesting paper on this subject, Mr. R. E. Lines stated that the best horse for the farmer in South Australia was that which he called a second-class draught. The high-class draught animal was usually too heavy and slow for the average farm work. For road work it was a very fine animal, but as three-fourths of the farmers' work consisted in cultivation, &c., it was better for him to have the horse best suited for this work. To keep up the class of animal it was essential that only the best sires should be utilised. As to feeding, he recommended good long hay placed in a roomy manger, but when the work being done was hard the feed should consist chiefly of chaff, with the addition of corn and bran, and oats in the summer when the weather was warm. Wheat or barley had a tendency to cause sores to break out on the shoulders. The animals should be provided with a roomy stable opening towards the north-east, the other sides being closed in, and plenty of yard room and drainage allowed. It was a mistake to tie up horses in the stables. Spring water was preferable wherever procurable, and he was not in favor of turning the animals out on every occasion when there was no work being done, such as on Sundays. It was better to feed them well in the stable, and so keep up their condition. Mr. Sargent, in discussing the subject, said that horses would eat long hay in the summer with more relish than they would in the winter, as it was more brittle and easily chewed. Mr. Peters did not think salt was necessary, especially if spring water were supplied for drinking. The practice of feeding long hay at night, when the horses had plenty of time at their disposal, was strongly recommended by Mr. Brayley. In reply to questions, Mr. Lines expressed the view that molasses was not necessary as an addition to the horse's ration.

Mount Bryan East, October 21.

(Average annual rainfall, $15\frac{1}{2}$ in.)

PRESENT.—Messrs. J. Thomas (chair), J. Doyle, W. Quinn, T. Quinn, H. and F. Tralaggan, Hughes, C. and G. Dare, F. Thomas, Gare, B. and W. Dunstan, P. Griffin, L. and B. Webber, R. Thomas (Hon. Sec.), and 20 visitors.

WOOL CLASSING.—Mr. Henshaw Jackson, the Wool Instructor, visited the district and gave a practical demonstration before a large attendance of woolgrowers at Messrs. Thomas and Gare's woolshed, kindly lent for the occasion. Several sheep were shorn, and the fleeces were skirted and classed. The advantages to the grower and the advantages to the woolbuyer were explained. The demonstration was of an enthusiastic nature, and great interest was taken by all present. In the evening Mr. Jackson delivered a lecture, which was also well attended.

North Booborowie, September 3.

PRESENT.—Messrs. Ashby (chair), W. Giles, Hannaford, Sullivan, Tall, Smart, Morgan, Roberts, Dunstan Simpson (Hon. Sec.), and one visitor.

FRUIT-GROWING.—Two papers on this subject were read. Mr. W. Giles said—"Land for fruit-growing should be well fenced with four plain wires and 3ft. wire netting to protect the young trees from hares and rabbits. It should be thoroughly broken up to a depth of at least 12in. or 15in. The subsoil should be broken through in sinking the holes in order to allow the roots to go down, and also to allow any water that is likely to accumulate to drain away quickly. If the land is wet, or water has a tendency to lie about on it, underground drains should be put in. The greatest care should be taken that the bud or the last working in the nursery is not covered with soil. Especially should this be watched in the case of apple trees. Apple trees are worked on blight-proof stocks, but the different varieties of apples are not blight-proof. Stone fruit trees do not need to be planted so far apart as is necessary with pears, apples, &c. The septuple system of planting is the best to adopt. The trees are then straight all ways, which means a great deal in the cultivation of an orchard. For home use I would suggest planting Cleopatra apples for eating, cooking, or jelly; Jonathan, for eating; Gravenstein, Rome Beauty, and Dunn Seedling for general purposes; and there are many others that could be mentioned. With pears, Duchers are best for eating, and Vicar of Winkfield for eating and cooking. The trees need to be pruned hard during the first two years to allow of their making roots. They must not have too much top for the roots. I would suggest cutting back to at least the third or fourth bud at the first pruning. Always be careful to prune to an outward bud to encourage the tree to spread out. In the case of a low limb, prune to a top bud in order not to encourage the limb to go down. Cut the centre limb out and so keep the tree open." Mr. W. B. Ashby's paper read as follows:—"One of the most important matters in connection with the successful planting of a garden is that each fruit should be planted on ground suitable to that particular variety. Apricots, peaches, nectarines, cherries, etc., should, as far as possible, be planted on a loose deep ground with good drainage underneath, or on limestone ground. I have found that in a tight ground with clay subsoil a great percentage of the trees die, and those that survive the wet and cold seem to bear very light crops of fruit more subject to disease. The apple, pear, plum, quince, and suchlike, seem to thrive best on the stiffer land with clay subsoil. Pears, in particular, of the very best quality have been grown on poor gravelly ground. For citrus trees I prefer very deep loam with good drainage; but I have seen them thrive and bear very heavy crops on limestone ground where there is a good depth of soil on top. Provided the ground is deep enough, I would give it a good ploughing to a depth of from 8in. to 10in. during the winter before planting to get plenty of moisture into it. The best and cheapest method for planting is to strike the land out with a plough and throw the furrows out to a depth of about 6in. when coming back with the plough. Then get a piece of No. 10 wire, about 1ch. to 1½chs. long, and at every 15ft. place on it a piece of very thin wire. Stretch the wire at right angles across the furrows, and each piece of small wire should hang over the middle of a furrow where the tree or vine should be planted. Spread the roots well around and place earth well over them; then press it down with the feet: fill to ground level. After planting one row, shift the wire on another 15ft., and so on till finished. The best time to plant in this district is July. Select good medium-sized trees. To prune young trees, cut them off about 15in. from the ground, as it is important that they should be low to prevent damage from wind, neither are ladders required to gather the fruit. This will leave the crown or main limbs about 12in. from the ground. They should be thinned out to four, and next season cut back to about 10in., the two top buds being across; this will give eight main limbs. Next season cut back similarly, which will give 16 main limbs, which is sufficient. Cut these back to a reasonable length, and for apples and pears spur prune to two or three buds. A well pruned apricot or peach should resemble an umbrella; an apple or pear, a wineglass. The transplanting of citrus trees should be done when the trees are becoming active, either in the spring or autumn. Great care should be taken in removing them from the nursery. It is best to have a ball of earth covered with a piece of bagging around the roots. Place the tree into position before removing bagging, and do not disturb the earth. Gently press the soil around it, then water. After the water has soaked away, fill it up to ground level. The best time to prune is in the spring. Paint all cuts over ¼in. thick." Mr. Roberts drew attention to the fact that Messrs. Giles and Ashby, who come from Clarendon and Clare respectively, each advocated severe pruning. He was doubtful whether severe pruning would be suitable for this district, as his experience was that in the north it

frequently killed the trees. The opinion was expressed that it was essential to plough the ground deeply and to keep it well worked; also that large holes in which to plant trees were unnecessary.

North Booborowie, September 28.

PRESENT.—Messrs. Ashby (chair), Canny, McColive, Roberts, Schaefer, W. C. and F. C. Catt, Hannaford, W. and A. S. Toll, Morgan, Warner, Smart, McQuillan, Mayfield, Dunstan, Clark, A. V. Simpson (Hon. Sec.), and seven visitors.

FALLOW.—Mr. A. S. Toll read a paper on this subject, in which he stated that to obtain a good yield of wheat it was necessary to thoroughly cultivate the fallow. The first ploughing for fallow should be about 4in. deep. The two principal reasons for fallowing were to eradicate all weeds and to conserve moisture. Fallowing in this district should be commenced as early as possible in June, and should be completed early in September. Before the fallow had time to set it should be harrowed twice, or if possible three times, with set harrows. The land would then be fairly fine on top but would not have the necessary depth of tilth. The weeds would have commenced to grow by October, and the fallow should then be cultivated to a depth of 2½in. but not more than 3in. He preferred the paring plough for cultivating, as it turned the soil well, cutting and turning the weeds, leaving no hollows or tire dragging ruts. After cultivating the fallow should be cross-harrowed twice. The land would then have the necessary fine tilth on top and would have a firm subsoil. Sheep should be allowed to run on fallow in order to keep down any weeds that might grow. Fallow should not be worked during the summer, but it was advisable to harrow after rains in March and April. If the fallow were cloddy it should be rolled and harrowed at this period. The fallow should be harrowed whenever possible after rain. In the discussion which followed several members were of the opinion that new land in this district should not be ploughed more than 2in. deep, while other members favored ploughing to a depth of 4in. Mr. Hannaford mentioned a case where 4in. ploughing, properly worked, had produced far better results than 2in. ploughing. In reply to a question Mr. Toll stated that under no circumstances should fallow be worked during December, January, or February. Several members, however, favored working fallow at any time in the summer after a good fall of rain.

Port Broughton, October 25.

(Average annual rainfall, 14in.)

PRESENT.—Messrs. C. E. Pattingale (chair), W. R. and H. P. Whittaker, T. E. Pattingale, R. Hill, B. Donnelly, W. Excell, D. and E. Allchurch, G. H. Rantley, and J. H. Fletcher (Hon. Sec.).

TAKEALL.—Following the reading of an article on this subject, an interesting discussion took place. It was remarked that takeall was not so prevalent this year as was usually the case, which was attributed to the unfavorable weather conditions to the growth of the fungus. Mr. G. E. Pattingale described the shape in which the patches of this fungus generally developed. In rubbly soil it had a tendency to long strips, while on drift sand it generally appeared in the whitehead form.

MORTALITY AMONG BROOD MARES.—Mr. G. E. Pattingale drew attention to the fact that there was more trouble with brood mares in dry seasons than was otherwise the case. It was generally found that the foals made abnormal presentation, in the majority of cases being upside down. Three members of the Bureau had lost mares this year, and in each case it was found that the foals were dead when the mares were first noticed to be out of normal condition.

Redhill, August 27.

(Average annual rainfall, 16½in.)

PRESENT.—Messrs. McAvaney (chair), Stone, D., E., and B. Steele, Hayes, Trowren, Treloar, Button, Dick, Holmes, Briggs, Pengilly, F. and F. A. Wheaton (Hon. Sec.), and three visitors.

MOTOR POWER ON THE FARM.—Mr. Trowren, in a paper on this subject, stated that farmers were beginning to see the advantage of engines for different farm work, such

as chaff-cutting. Gasolene engines were generally considered the cheaper and handier. With the oil engine it was necessary to heat it before commencing, and if it became necessary to sharpen the knives of the chaffcutter, or to stop for a few moments for any other reason, it entailed letting the engine run empty or keeping the lamp burning. On the other hand, the gasolene engine was always ready to commence work. Work could be stopped without any waste of fuel or time. Generally, to drive a four-cutter and elevator a 6-horsepower oil engine was required, whereas a 4-horsepower gasolene engine would do the same work. The gasolene engine which the writer had was capable of cutting from 12 tons to 14 tons of hay on 4galls. of fuel, which was equal to about 5d. per ton. Where the country was suitable the use of tractors was advisable, and here again the gasolene engine was the best. The oil engine lost its power when it became overheated; on the other hand the gasolene engine worked better the warmer it became. In addition there was no bare flame, the engines were cleaner, and generally did their work better. Continuing, the paper said: "Kerosine gives off a lot of smoke which cause the valves and combustion chamber to become clogged. These have, of course, to be cleaned. Our engines have very seldom to be cleaned for this reason. We have taken the piston and valves out, but they have needed very little attention. The strength of our engines is obtained from the great length of the cylinder and the narrow space for combustion. Power is obtained from the combustion of an explosive mixture of gasolene and air automatically admitted into the cylinder. The requisite compression having been obtained, the mixture is ignited by a spark from the battery or magneto, and the impulse of this explosion furnishes the power to drive the piston connected with the crank. Our engines are what are known as four-cycle engines. In the operation four strokes of the piston are required to first draw in a charge of fuel, secondly compress it, thirdly ignite it, and fourthly discharge. We plough with the tractor at a cost of 2s. 9d. per acre. This is very little cheaper than horses, but the advantage of the tractor is that there is no extra expense while it is not working, and it does not require so much labor. Of course, these engines are not perfect, but the time will come when all work will be done on the farm with electricity." In discussing the subject, Mr. Stone expressed the view that tractors would be very popular for farm work in the course of a few years. Mr. Pengilley thought the practice of using tractors on the farm would be inimical to the interests of the horse-breeding and chaff industries, and he opposed them on this ground. Most members were of the opinion that a 20-horsepower tractor would not do the work of 20 horses, with which Mr. Stone disagreed.

Redhill, October 1.

(Average annual rainfall, 16½in.)

PRESENT.—Messrs. McAvaney (chair), Button, Kelly, Pengilley, Holmes, T. A. Wheaton (Hon. Sec.).

FARM HORSES.—Following on the report of delegates to Congress, members discussed the paper on farm horses, read by Mr. W. P. Foulis. Members generally agreed that the type of horse advocated was too large for farm work, and the smaller type was fast coming into prominence. Members thought the Suffolk Punch would be used more in future. Other matters brought up at Congress were discussed, and it was decided to put into operation a few suggestions made by the Secretary of the Advisory Board for the better working of the Branch.

Spalding, October 18.

PRESENT.—Messrs. E. E. Gill (chair), G. Thorn, D. Work, A. B. Jones, P. H. Gill, W. Hacklin, J. H. Pluckrose, and two visitors.

FALLOWING.—This subject was dealt with in the following paper by Mr. P. H. Gill:—"Most farmers find it most convenient to begin fallowing as soon as seeding is over. The way in which the paddock is worked depends a good deal on the shape and contour of the land. It is best to have the lands or pieces as long as possible and the same width each end, to prevent short work and much turning, as this not only tires the team but takes much more time. If the land is on a slope I would advise fallowing the highest ground first, so that the water is held from running off the hill sides on to that already fallowed, causing it to become boggy. Where possible it should be fallowed along the slope, to avoid creeks or gutters. The depth to fallow is one of most important questions and is worthy of much discussion. Some farmers fallow deep, some to a medium depth,

while others only scratch the ground. 'Each one seems to be able to put forth plenty of arguments to suit his own peculiar way. The depth depends considerably on the class of soil; that which suits one place may not suit another. I am of the opinion that in this district no ground should be fallowed to a less depth than 4in. or more than 6in. Between 4in. and 5in. is best, but nothing less than 4in. Only that area which the farmer is able to work well with harrows and the cultivator before harvest time should be fallowed. A great many farmers pay too much attention to quantity and neglect the quality. This is a great mistake, because frequently 250 acres of well-worked fallow and properly-tilled land will produce more wheat than 400 acres of neglected fallow and badly put in ground. This question is worthy of consideration. Remember the high price of land, the extra seed and super., and the extra quantity of land to be gone over with the harvester, to say nothing of the land becoming dirty. Some farmers are very much against doing anything to the land after fallowing more than harrowing and feeding it off with sheep, and they claim to grow as much wheat per acre as those who use the cultivator. This method may answer in some districts, but after practising both ways I have come to the conclusion that the more work the fallow gets the better. After finishing fallowing, say at the end of August, apply harrows; or the clod crusher, if necessary, should be put over to level it. Then graze with sheep to check the weeds; remove all loose stones, cultivate across the furrows if possible, and if time permits again cross cultivate. Have good fallow well worked, the very best graded seed procurable, give it a good dressing with super., say between 80lbs. and 100lbs. to the acre, and till carefully, after rain if possible.' In discussing the paper Mr. Thorn emphasized the necessity of fallowing early. Five inches was the most suitable depth. Mr. Work thought the time to fallow depended on the nature of the soil and the strength available for working it. Where red land was cultivated to too fine a tilth after heavy rain the surface would set too hard for a good growth. Mr. A. B. Jones believed repeated harrowing was beneficial. Weeds should be kept down well and heavy dressings of super. applied at seeding time. Mr. W. Hacklin thought that while black loam improved with working, too much cultivation was not good for red soil.

Whyte-Yarcowie, September 23.

(Average annual rainfall, 13½ in.)

PRESENT.—Messrs. G. F. Jenkins (chair), G. A. Wittwer, J. E. and F. Hunt, A. Mitchell, G. R. and J. Mudge, S. Robinson, W. Mudge, J. McLeod, J. Faulkner, E. Travers, F. Lock, J. Walsh, E. J. and F. Pearce (Hon. Sec.), and two visitors.

CLEANLINESS IN DAIRYING.—Mr. G. A. Wittwer read an extract dealing with the use of separators from the *New Zealand Farm and Stock Journal*. The construction of well-ventilated separating houses was urged. Cream cans without seams were recommended, and the necessity for thorough scrubbing and scalding was emphasized. Mr. Wittwer then expressed the opinion that more strict supervision was needed among the dairymen, particularly to bring about greater cleanliness in the use of separators and butter-making generally. Several instances had come under his personal notice in which the product of the dairy, which the storekeeper for business reasons was practically compelled to take from his customers, were far from clean, and in some instances were quite unfit for human consumption.

LOWER-NORTH DISTRICT.

(ADELAIDE TO FARRELL'S FLAT.)

Blyth, October 19.

PRESENT.—Messrs. A. L. McEwin (chair), J. S. McEwin, C. H. Zweek, M. Coleman, J. C. and A. S. Schulze, W. J. Ninnos, R. Buzacott, C. Lehmann, S. G. Shepherd, M. Williams, D. Crawford, jun., J. B., F. A., and A. B. Kirchner, J. and T. Williams, H. Neumann, H. A. Montgomery, J. Kostera, E. C. Deland, W. O. Eime (Hon. Sec.), and five visitors.

HORSE-BREEDING SOCIETIES.—This subject was dealt with in a paper by Mr. E. Lehmann, in the course of which he stated that the introduction of the proposed horse-breeding societies' scheme should result in a considerable improvement in the quality of the horse stock in this State. It should be a means of inducing owners to introduce first-class stallions from the eastern States and New Zealand. The Branch decided to discuss the matter fully at its next meeting.

Freeling, August 28.

(Average annual rainfall, 17½ in.)

PRESENT.—Messrs. A. J. Kuhlmann (chair), F. H. Heinrich, J. T. Elix, A. Elix, Neindorf, Savage, A. Anders, Noske, Gramp, Morris, M. Shanahan, W. Schuster, J. Kuhlmann, G. A. Block (Hon. Sec.).

A MODEL POULTRY FARM.—The meeting was held at the homestead of Mr. F. H. Heinrich, and an inspection of the model poultry plant was made. Mr. Heinrich put up the plant 18 months ago. After some trouble he secured a competent manager, and he believed he would be able to say at this time next year that the business was profitable. Poultry-farming, like any other business, required any amount of energy. The most important factors were good housing, feeding, watering, and cleanliness. Greenfeed during the summer was particularly desirable, and in order to obtain this a good supply of water was necessary. Farmers, by paying a little more attention to poultry and working on the proper lines, could increase the income of the farm very considerably.

BERSEEM.—A plot of about three-quarters of an acre of Berseem (Egyptian clover), the second growth, was inspected. Mr. Heinrich spoke very highly of this as a fodder for poultry and cattle. He mentioned that the stem was so succulent that the poultry ate that as well as the foliage.

Freeling, September 28.

(Average annual rainfall, 17½ in.)

PRESENT.—Messrs. A. Kuhlmann (chair), A. Elix, G. T. Elix, J. Kuhlmann, E. Morris, W. Schroder, H. Kohde, Ch. Dahlenburg, and G. A. Block (Hon. Sec.).

WHEAT AND OATS FOR HAY.—This subject was dealt with in the following paper by Mr. A. Kuhlmann:—"For 19 years I have carried on farming in this district with a certain amount of success, due, no doubt, to the application of improved methods of farming. During the greater part of this period I have tried various experiments in regard to pickling, depth of sowing, methods of tillage, in altering farming implements, and mode of sowing. My present method of farming is to crop half of my land every year. The whole of the other half, except 11 acres, is under fallow. I believe in fallowing early in order to give the land as long a spell as possible. The depth of ploughing is about 4 in., but soon after this operation the land is harrowed at right angles to the ploughing and then scarified across the ploughing. The workings are repeated when occasion arises, but soon after Christmas the fallow is skimmed with a scarifier especially made to my order. It is of great importance that the scarifying about this time of the year should be shallow, in order to kill the weeds, but prevent the moisture in the land escaping too rapidly. Near the end of March, irrespective of weather conditions, the land is once more scarified, or chisel-harrowed, and the manure, lwnt, to the acre, is drilled in. This should never be done too early in the season; not more than three or four weeks before the wheat is sown, because the weeds that grow before the wheat is sown will feed on the manure, to the detriment of the wheat. During April or May, according to the suitability of the season, the all-important operation of sowing the wheat and oats takes place after the fallow has for the last time been scarified very shallowly and harrowed. When sowing I remove all the tines from the drill and only leave the tubes. The wheat does not fall in drills but is more scattered, especially on windy days. Thus it is more evenly sown and each grain has more room to stool. There is less danger of the crop suffering from smut, and the grain does not come in too close contact with the manure. The whole crop is cleaner and almost free of weeds, because there is little room for the weeds to grow, and finally the yield is much heavier than when the seed is sown with tines on the drill. When the wheat is sown with the manure through the drill there is more trouble with smut. Shortly after the sowing is completed the land is rolled. One hundred acres are rolled in one day by a single team of horses. Although this seems too much for the horses, it is not so in the way I work them. I couple three rollers 11 ft. wide,

and these are kept moving for the whole day without a stop. I roll with six horses for some hours, then three of these horses are released and fed and three fresh horses take their places. This is repeated during the whole day, and while the man in charge of the team in the morning has his dinner another man takes his place. The soil is in perfect condition now, for it has been four times scarified, three times harrowed, and rolled. The wheat as well as the oats which is sown is most carefully graded and freed from all foreign matter and seeds. Only large plump grain is selected. I do not believe in sowing one kind of wheat only, but after experimenting with many I find that the five following varieties the best for hay, viz. :—Baroota Wonder, White Tuscan, Leather Head, Majestic, and Le Huguenot, and one kind of oats—Calcutta Cape. I sow one-third of every paddock put in crop with oats ; the next third is sown with oats when the paddock is in crop again, and the last third at the next sowing. I find that wheat which follows a crop of oats yields one-half to three-quarters of a ton of hay more than if it follows wheat again. In order to make the oats stand up better I add $\frac{1}{2}$ bush. of wheat per acre and mix it with the oats seed. When experimenting with 'rotation of crops,' I observed regularly that wheat sown on land where barley had been one or two years ago yielded a much inferior crop. The difference was as much as one ton of hay to the acre, or even greater. I have averaged a yield of $2\frac{1}{2}$ to 4 tons of hay to the acre for years. Even the last season's crop averaged 2 tons, although it had been rather dry and otherwise unfavorable to the production of a heavy crop. I keep just as much stock on my land as other farmers, and know how to keep them in good condition with less hay from the stack than others do. For this purpose I have reserved 11 acres of land which is cropped every year. This piece of land is well manured with stable manure and superphosphate, and sown with equal quantities of barley and wheat in March, or as soon as the first rains come. It gets an early start, and by the time the last of the following is done I have good feed for my stock till harvest time." Members generally agreed that the varieties mentioned by the Chairman were suitable hay wheats, but they were not heavy grain-yielding kinds. Mr. W. Schuster expressed the view that Marshall's Prolific was one of the best hay sorts.

Freeling, October 25.

(Average annual rainfall, 17 $\frac{1}{2}$ in.)

PRESENT.—Messesrs. J. A. Kuhlmann (chair), Neldner, Aug. Mattiske, sen., H. Mattiske, jun., Theo. Elix, W. Neindorf, H. Koch, M. Shanahan, John Kuhlmann, F. H. Heinrich, G. A. Block, (Hon. Sec.), and one visitor.

SELECTION OF SEED WHEAT.—The Hon. Secretary gave the following paper :—
 "The Government recognises the value of the Agricultural Bureau to the State, as is shown by the encouragement it gives to farmers to form new branches. Questions of importance to farmers are referred back to the Branches for report, and much valuable information is collected thereby. Naturally we question ourselves as to how we can still further improve the usefulness of the Agricultural Bureaux. My answer thereto would be to devote more time to experimental work. In all different branches of human knowledge experiments are continually carried on ; very often grave mistakes have been made, but without these experiments there would have been no progress. The same applies to agriculture, and I am sure each farmer can give a whole list of the mistakes he has himself made, such as planting the wrong varieties of trees or vines, keeping the less profitable breed of sheep, pigs, or poultry, sowing varieties of wheat affected with rust when he should have sown rust-resisting wheat, or putting in wheat that will not stool or kinds that will shake. In this paper I am going to confine myself to improvements in seed wheats, and how they should be effected through the different Branches of the Agricultural Bureau. During the last few years such work has been carried on at Roseworthy and at Parafield, and a number of farmers have been taking it up on their own. Much good has been done by selecting from known varieties as well as introducing new ones, but a great deal more can be done by members of the Bureau. The main point is to get our farmers interested in the work. My suggestion is to give prizes for the best 30 or 50 heads of a known or unknown variety ; special prizes might be given for the best and largest head of wheat. This matter might be taken up by the teachers of our schools, and besides the possibility of growing new varieties, it would be the means of giving the children an interest in agriculture. The different varieties could be then numbered and judged by a competent judge, the Branch taking possession of the wheat and making arrangements with some farmer to sow the different sorts side by side. After that results could be watched and new selections made at

harvest time. The prize-money could be paid out of the funds of the different Branches. Now if the 140 Branches we have in the State were to take up this matter in the way I suggest, results would certainly be very satisfactory. Members may say these experiments are now carried on under the supervision of experts, but nearly all new varieties of wheat have been introduced by different individual farmers. Then again farmers may say there is nothing new in this suggestion: it is now carried on at Balaklava under the auspices of that Branch. But at Balaklava the competitors commence with a quarter acre, while I suggest, if there is no more available, commencing with a single head. There each one sows on his own ground; one farmer may sow an early variety, another a later one. One may use more super., the other less." Mr. Heinrich, in discussing the subject, expressed an opinion in favor of hand selection, which, he said, was being satisfactorily carried out at Roseworthy. Mr. Neindorf was in favor of individual farmers doing more in this direction, in which he was supported by Mr. Elix, who had selected from a single head a variety which had proved very satisfactory.

Greenock, September 27.

PRESENT.—MESSRS. A. Heinze (chair), R. Tümmel, Geo. Tümmel, L. Tümmel, J. C. Jaensch, A. Nitschke, B. Nitschke, W. F. Nitschke, H. Koch, E. Handke, C. Liersch, O. Semmler, E. Geyer, O. Krüger, W. Rönfeldt, E. Rönfeldt, W. B. Teebo, P. Kernich, S. Listner, W. Nenke, V. Koschade (Hon. Sec.).

THE PRODUCER AND PRODUCTION.—This subject formed the title of an interesting address by the Hon. Secretary. Attention was drawn to the necessity of imparting a thorough education to those who were to be the producers in the course of a few years, and due emphasis was given to the benefits derived from the application of scientific knowledge to agricultural problems.

Riverton, October 15.

(Average annual rainfall, 20½ in.)

PRESENT.—MESSRS. J. P. Schultz (chair), R. H. Cooper, R. Wilkinson, E. Johnson, W. Moss, W. B. Davis, R. J. James, H. A. Davis, J.P., J. W. Kelly, F. Phillips, and E. A. Gray (Hon. Sec.).

DOUBLE MANURING.—This subject was dealt with in the following paper by Mr. R. Wilkinson:—"The whole science of manuring plants is, to provide suitable food in a form available for their nourishment. A wrong impression exists regarding manures, i.e., that they are all merely forcing mixtures and exhausting to the soil, whereas a complete well-balanced manure feeds and supports the plant, asking nothing from the land except moisture, and therefore cannot injure the land in the slightest degree. It is in applying what is termed an acid manure, such as our every-day superphosphate, which only contains a portion of the required plant foods, that the danger lies. Manures may act in two ways. First—By actually supplying plant food; second—By acting chemically on food already in the ground and rendering it more soluble, and therefore more available to the plant. The former is a true manure in that it takes nothing from the land; the latter leaves it poorer than before. It is not enough to know that plants require certain substances, such as phosphoric acid, potash, lime, and others, but it is necessary to understand the proper management of these to obtain the most effective and economical results. To secure larger crops, phosphoric acid, potash, and lime should be used in greater quantities than crops require, but nitrogen, being a stimulant of great power, should be applied in amounts not in excess of the needs of the crop. One would think that in a district like our own where there is a good proportion of dark soil, rich in humus, and consequently containing a fair supply of nitrogen, thorough manuring would not be so necessary as in poorer and drier parts of the State. But the case is just the opposite, as the nitrogen acting on the plant growth as a stimulant must be backed up by a liberal supply of plant foods, unless we are to have a rank growth, deficient in mineral salts, very apt to lodge in bad weather and probably ending in a miserably shrivelled grain. There is a natural law in regard to plant nourishment, providing that no crop can assimilate more than half of the phosphoric acid available in the sod. This is important, in that it means that there must be twice as much available in the soil as the crop can possibly take up. It has been calculated that a 25bush. crop of wheat requires 17½lbs. of phosphoric acid, therefore there must be at least 35½lbs. available as food for the crop. Similarly a 40bush. crop requires 28½lbs., and must have at least an available supply of 57lbs. The question naturally arises, from where is this phos-

phoric acid to come? it being known that Australian soils are greatly deficient in natural phosphates. The answer is—By applying artificial phosphates having a form as near as possible to the natural soil phosphates, which according to the author of the 'A.B.C. of Rational Manuring,' can be done by his system—double manuring. The absolute necessity of phosphates to the human race, also to our stock, for the formation of healthy bone, teeth, and brain, makes the plentiful supply of phosphoric acid in the form of phosphates in the soil an essential to the healthy growth of nutritious grain for ourselves and fodder for stock. The lack of phosphoric acid in our soils becomes apparent when we compare the following figures:—The soils of Australia contain from 350lbs. to 1,100lbs. of phosphoric acid per acre, as against from 3,500lbs. to 4,300lbs. of the Canadian wheat farms, and the 5,200lbs. per acre of the Russian wheat soil. From calculations based upon recognised data relating to soil content, allowing for the replacements by manures applied to the soil, it is estimated that the phosphates in the older land of Australia under wheat will be exhausted in the next 25 to 35 years, unless the present rate of depletion is at once checked. The effects of the employment of an acid manure, such as our ordinary superphosphate which is made by the action of sulphuric acid on the natural rock phosphate, that sets up an acid reaction in the soil, cannot be beneficial, as the healthy and natural action of soils is alkaline. The action of 'super' on the phosphates of the soil causes them to become easily soluble, and thus quickly available to the plant as food. Now if the crop should utilise this increased supply of prepared food, it would represent a larger yield, but unfortunately the wheat plant cannot do this, because for the first two or three months after sprouting its growth is very slow, and thus the winter rains remove this valuable plant food by leaching and drainage, and it is lost to the crop. This waste of soil fertility is the direct outcome of using superphosphate by itself without another phosphatic manure containing lime, as is done by the European wheat-growers. Lime, in conjunction with the superphosphate, will arrest to a large extent the latter's harmful effects, but unfortunately the Australian soils are deficient in lime. The minimum lime contents should be 17,000lbs. per acre, whereas the average content of Australian soils is only 4,000lbs. per acre. The safeguard against the exhaustion of soils is a rational system of restoring to the land all the phosphoric acid taken by the crop in a natural form accompanied by carbonate of lime. With virgin soils sufficient time has elapsed to enable the moisture, air, cold, and heat to store up an available supply of phosphates in the soil against the needs of plants. This explains why the first few crops are as a rule heavy. But the rate of withdrawals of phosphates by crops is much greater than the conversion into available form of the supply by cultivation. In six months a good crop will take up the stored-up supply of six years. Consequently without suitable manurings a falling off of yields is bound to happen, since the available phosphates are being gradually exhausted. Thus, given moisture and humus from which to derive the required nitrogen, the problem of wheat-growing resolves itself into the supply of available phosphate. The double manuring system, according to the originator, is the solution of the manuring difficulty, and will result in crops half again as heavy as we are getting at the present time with only a slight increase of labor and outlay, and by the use of which the soils in years to come will be as productive as they are now. The practice consists of using small quantities, 30lbs. to 40lbs., of superphosphate, with the seed as a starter for the crop, but previous to this the fallow must be dressed after the first harrowing of the ploughed land with another phosphatic manure, preferably a good guano with its slight percentage of organic nitrogen. The quantity of manure to put on the fallow should be sufficient to provide enough phosphoric acid for the full crop desired. Thus a crop of 25bush, requiring 17½lbs. of phosphoric acid must have an available supply of 35½lbs. from which to draw, to supply which a dressing of just under 2cwts. of either phosphatic guano or Thomas phosphate, known as basic slag, will be necessary. These quantities may appear large, but they are nothing out of the way, and are perfectly safe in practice owing to the character of the manures. The working theories of double manuring are: First—That the phosphates in phosphatic guano or Thomas phosphate, being largely citrate soluble, are available for the plant when most needed, and thus allow it to take advantage of any moisture in the soil. Second—In utilising a small percentage of water soluble phosphates a large amount of plant food is reclaimed in the soil, which, had superphosphate been used by itself, would have been lost by drainage, &c. Third—By the presence of lime in these manures the alkaline action of the soil is maintained, the decomposition of stubble and all organic matter is hastened, thus making a valuable humus, which in turn greatly helps in conserving moisture, and lastly helps to kill out weeds, such as sorrel. As far as I know the true worth of this method of manuring has not, in this district at least, been tested. Although I cannot vouch for the practical value of the system, it seems well worthy of a thorough trial."

YORKE PENINSULA DISTRICT. (TO BUTE.)

Maitland, October 5.

(Average annual rainfall, 19½ in.)

PRESENT.—Messrs. Smith (chair), Bawden, Hielemann, Hill, E. G. Jarrett, A. Jarrett, Wundersitz, and Pitcher (Hon. Sec.).

COLT-BREAKING.—The following paper on this subject was read by the Hon. Secretary :—“The best time to break in a young draught horse is at the age of two and a half or three years. The horses should be yarded as quietly as possible, and it does not pay to hurry over the work. A light pole 10ft. or 12ft. long should be used for placing a rope on the animal's neck. Care should be taken that the spare rope is properly coiled, so that it can be handled easily and paid out without any danger of entangling the operator. I prefer a running noose for the neck. When the rope is fixed on the animal's neck the assistant should take one turn round the strongest post available, and by degrees it should be worked up to the post. The colt will probably choke down in its endeavors to get free, but this will do no harm. The next thing is to put on the halter. The rope should be slackened from the post before handling the colt is attempted. One hand should be held before its nostril, in order that it may smell the operator. By this time he will have found out whether the colt is active with its front feet. Having been stroked and patted, a good strong plain bit should be put in its mouth and the rope untied from the post. If the colt is at all wild a reef should be taken through both sides of the bit and put round the neck in a firm knot, and a lighter rope placed on the opposite side to that which the operator is to hold. The collar and hames should then be put on. The operator with the strong rope should lead out of the yard and get the colt to follow him. If dubious, the assistant with the light rope should try very quietly to drive it by throwing the rope over its back and bringing it round his hind legs. The rope can be used for checking the animal if it makes a rush. A piece of well-worked fallow should be selected, as it gives the operator a good foothold. The next procedure is to lunge it. If the beast is willing this operation need not be continued for more than five or ten minutes. The colt should then be drawn towards the breaker. It will soon stand, and it should then be coaxed up to the operator. It may not do this at first, but it will not be a lengthy undertaking. The rope should then be changed from side to side and the colt run round a few times. If it declines, the assistant with the light rope can coax it by putting the rope round its hind legs, which the majority of horses resent. Old horses are liable to get their legs over the chains, and it is therefore necessary to teach the colts to become accustomed to having things about their legs. Before going back to the yard the first lesson in leading should be given. The operator should go ahead and coax, but not pull on the rope. The assistant will start the animal from the rear and gradually fall back as it moves away. The colt will not lead immediately, but will very quickly learn, especially if handled quietly. The first lesson in backing should also be given. If the animal moves one front foot it is quite enough for a start. It should then be taken back to the yard, where a few minutes should be spent in patting and talking to it, and if fairly quiet the gear taken off. If two have been handled in the morning the same two should be handled in the afternoon. A pair of leading chains without a spreader should be obtained. The object of leading chains is to prevent the animal kicking the swing. The animal should be fixed on to a light log in chains, and the operator should go ahead, the assistant keeping behind. Care must be taken to have the ropes neatly coiled. The operator should gradually work behind and keep going if possible for about half a mile. Then stop and loosen all ropes that are jamming the animal's jaw or chafing. It should then be driven as straight as possible and turned first one way and then the other, and turned back quite short, so that the chains rub against its legs. It does not matter if it gets its legs out. It will soon know whether its legs are more comfortable inside the chains or out. Next morning it should be taken out, but with an old and reliable horse for company. They should be yoked up as a pair and given from an hour to an hour and a half exercise on the same lines as when working the colt singly. The third day it should be worked in the team, but always on the near side for a commencement. I prefer separate reins on the colt. After working on the near side for a week or two it should be changed to the off side and taught the use of the reins on both sides. When it has learnt this it may be used in the body, as the case may require. If convenient it should be worked for about two hours for the first few days. The time can then be extended to half a day. If possible it should not be worked for more than half a day for the first season, as the animal is young and tender and requires consideration.” In the discussion which followed

Mr. Heilemann thought the sooner young horses were put in the team the better. He did not believe in wasting a lot of time over them. Mr. Hill always put a colt between two quiet horses and gave it exercise. He then schooled it in the wagon. Mr. Bawden believed in kindness, and considered a closed shed the best place in which to handle a colt. He did not believe in drawing a colt up to a post, as large numbers of colts lost their lives in this way, with which view Mr. Smith agreed.

Moonta, September 24.

(Average annual rainfall, 15in.)

PRESENT.—Messrs. J. Atkinson (chair), H. Fuss, R. A. Hancock, W. F. Ortloff, S. S. Woodward, W. B. Stacey, F. E. and C. Nankivell, T. R. Luke, J. Cooper, T. Laidlaw (Hon. Sec.), and one visitor.

PLOUGHING.—Mr. R. A. Hancock read a paper on this subject, in which he stated that to facilitate ploughing the horses should be yoked as close to the plough as it was possible. This was done by shortening the traces, S hooks, and swings as much as possible, and the spreader bars should also be kept short. This kept the horses close to the work, made the load easier to draw, occasioned fewer sore shoulders, and kept the horses in better condition. For ploughing the first time he advocated going round the paddock with the left hand to the fence, the front body just skimming the ground and the hind body ploughing to the required depth. He would then turn round and plough with the off front wheel of the plough in the furrow made by the hind body, thus filling in the furrow made by the hind body. The hind body would then be cutting the ground at the required depth. This could be done with half the team, so allowing the plough to get close to the fence, and would prevent raising an embankment at the outside edge, which would be found detrimental when rolling and cutting. By commencing the paddocks in this way the land was kept level. He found it easier to keep the ground level than it was to level it after it had been raised in furrows or embankments. When ploughing the paddocks in lands he advocated striking out in the same manner. The plough would then cut all the ground at the crown and would finish with the hind body just skimming the ground, and not leaving a deep finishing furrow, which was never properly filled in. In the discussion which followed Mr. Stacey said he would not keep the horses too close to the plough, as in crab hole and Bay of Biscay ground the longer draught the better the ploughing would be. Neither Mr. Stacey nor Mr. Ortloff would plough nearer than 6ft. from the fence, so that cattle could not reach the crop. If they once learned that trick they became a nuisance. Mr. Hancock would place a barbed wire on the top of fences to prevent cattle reaching over.

Moonta, October 14.

(Average annual rainfall, 15in.)

PRESENT.—Messrs. J. Atkinson (chair), J. Cooper, T. R. Luke, C. Nankivell, H. Fuss, W. F. Ortloff, J. Andrewartha, S. S. Woodward, S. J. Griffin, W. B. Stacey, T. Laidlaw (Hon. Sec.), and one visitor.

FALLOWING.—Mr. J. Cooper read a paper on this subject. The chief value of fallowing, he said, was to liberate the plant food stored in the soil as organic matter. Ploughing and stirring admitted air, which helped to replace the nitrogen taken from the soil by the previous crops. It also destroyed the roots of weeds and converted them into fertilising material and allowed the ground to recuperate. Fallowing should be commenced as soon after seeding as possible. He advocated ploughing to a depth of 3in. or 4in. in this district, but where the subsoil would allow of it 6in. was preferable. He advised ploughing all fallow in two chain or smaller lands, as then the soil was thoroughly worked when cross-ploughed. He would cross-harrow immediately after the first ploughing had been finished. This levelled the surface and checked evaporation of moisture. The fallow could be harrowed after it had been turned back. When the first ploughing had been completed he would take off the mouldboards and set the plough to 6in. or 8in. and then cross-plough. This would stir all the subsoil without bringing it to the surface. Where the soil was heavy he would harrow well, but where it was sandy he would work as little as possible for fear of drift. In the discussion which followed Mr. F. Ortloff said he did not

favor deep ploughing; 6in. was too deep, 3in. being quite deep enough for the soils in this district. Deep ploughing encouraged takeall. In the summer the fallow should only be lightly skimmed in order to just cover weed seeds. A light rain would then cause them to germinate. Mr. S. S. Woodward did not favor deep ploughing. He had fallowed in the summer and had turned it back in the spring, and it gave promise of being his best crop this year. Mr. J. Atkinson believed in taking off the mouldboards and ploughing deep without turning the subsoil. It would then make a better seed bed. Mr. C. Nankivell said that takeall and black rust were more noticeable where the land had been ploughed deep. Mr. J. Cooper preferred the skim plough to the V-shaped cultivator or scarifier for working back fallow.

SORE SHOULDERS.—In a discussion on this subject Mr. J. Atkinson said that when he ploughed in lands of a chain to two chains some years ago he noticed that sore shoulders were not so prevalent among horses as they were with the block ploughing. He attributed this to the fact that the air got between the collar and the animal's shoulder when turning. C. Nankivell considered that farmers should oil their horse collars and keep them clean. The horses should be kept in proper condition and good feed, not too rich, with an occasional bran mash, should be given them. The shoulders should be properly brushed and groomed. If this were done they would not be troubled with sore shoulders. He had teams working all the year round in farm dray and wagon, and there was no sign of sore shoulders on his horses. Mr. B. Stacey said that lack of grooming and badly-fitting collars were not the only causes of this trouble. It was often caused by a microbe under the skin, which if not killed would endeavor to eat its way out, and thus cause a sore. When the lumps, which were a sure sign of the insects' presence, first appeared a strong lotion of sulphate of copper should be applied. This would kill the insect, and thus prevent a sore.

NOXIOUS WEEDS.—Mr. Orloff expressed the view that the wild turnip should be classed as a noxious weed. It was spreading very rapidly, and farmers would experience great difficulty in eradicating it. Mr. B. Stacey said that the Cape tulip, three-cornered jacks, and other poisonous weeds were spreading very quickly in the district. No regard was being given them by the district council or by the farmers generally. The tulip was growing so thickly that hardly any grass would grow near it. The grass that did grow was not fit for stock to eat, as it came into contact with the milk from the tulip. A horse had died quite recently through eating the weed. He considered that a date should be fixed by the Government on which every person should commence destroying weeds. A ranger should be appointed to see that those having noxious weeds on their property destroyed them. If this were done they would soon have the weeds eradicated. It was useless one person attempting to destroy them when perhaps his neighbors allowed them to seed and spread everywhere. The Cape tulip bloomed three times a year. It was dangerous to children, for when picking the flowers they got the milk over their hands, and this was likely to be transmitted to their mouths with disastrous results.

Pine Forest, September 24.

(Average annual rainfall, 13in.)

PRESENT.—Messrs. Attenborough (chair), C. Schultz, S. Barr, R. Goodridge (Hon. Sec.), and one visitor.

CONGRESS ECHOES.—Having heard the reports of delegates to Congress, some of the members decided to try small plots of six-row barley next season. They thought, however, that wheat would not do as well after barley as it would after wheat. Oats were profitable to grow, only in dry seasons they were not good for a hay cut. Members also decided to act on the advice of Professor Lowrie by using the harrows more and the cultivator less, and, where the conditions would permit of it, by ploughing in stubble instead of burning it.

FRUIT AND FLOWERS.—Members inspected the property of Mr. Attenborough, at whose farm the meeting was held, and were much impressed by the success achieved with fruit trees and with flowers in this part of the country, which in earlier years had been commonly called the desert. A useful barn was seen built with stone in the side of a hill, the top storey being used for seed and super., with a platform arranged the right height for the wagon, and the bottom storey being used as a trap shed.

WESTERN DISTRICT.

Koppio, September 26.

(Average annual rainfall, 22·35in.)

PRESENT.—Messrs. G. B. Gardner (chair), J. Newell, T. Brennand, G. and M. Howard, C. Barraud, M. T. Gardner (Hon. Sec.).

EXHIBITS.—Mr. M. Howard tabled samples of three-year-old Chou Moellier root, and also a sample of sea kale. Samples of early-sown field peas were tabled by Mr. Brennan, and late-sown peas were exhibited by the Hon. Secretary. The early-sown peas showed much better growth than the later sown, and members generally agreed that to be profitable peas should be sown early in this district. The first fortnight in June was considered the best time.

WORK IN THE ORCHARD.—Mr. G. Howard read a paper on this subject, in which he stated that August should be a very busy month for orchardists. The vines should be the first to be pruned. A method of discovering whether the vines were ready for pruning was to cut three or four vines of different varieties in each row. The vines which showed no sign of bleeding could be pruned immediately, and the others left till a future date. Vines intended for trellising should be cut accordingly and all cuttings carried away. Manures should be applied to vines that had not made much growth. Peach and apricot trees should be pruned after the vines, and manure should also be applied to those of slow growth. Pruning should be finished by the end of the month and ploughing commenced, and a little later on it should be harrowed. Peach trees should be sprayed just as the buds were bursting. In the discussion which followed, Mr. Barraud contended that in a large orchard pruning should be commenced before August. Members generally considered it advisable to work the land as much as possible. Mr. Howard had used several varieties of manures, but he had had best results from the special orchard manure, and he thought this the cheapest to apply. Mr. J. Newell would not work the land deeply near the trees for fear of damaging the roots.

Miltale, September 21.

(Average annual rainfall, 14½in.)

PRESENT.—Messrs. E. P. Smith (chair), J. S. Jacobs, J. P. Story, A. R. S. Ramsey, E. Story, H. R. Jacobs, C. E. and S. R. Searle, T. A. and M. H. Wilson, W. E. Hier (Hon. Sec.), and four visitors.

IMPLEMENTS, STOCK, AND CROPS.—The following paper was read by Mr. E. Story:—“Efficiency and economy are the two main factors in successful farming; neither one must be sacrificed for the other, each is equally important. The farmer must always study which is cheapest and best in the long run. Now, for instance, a blacksmith's outfit will cost a farmer a few pounds, but if his farm is without one it will soon cost him a good deal of time and money in running to the local blacksmith with his picks, crowbars, broken machinery, &c. If he has a shop, on wet days he can furnish his farm with swings, hooks, &c., and also sharpen his ploughshares. He should have sheds for all his machinery, and all implements should be housed as soon as they have finished their work for the year. I would draw special attention to the binder, as it seems to be the shortest-lived machine on a farm. Most farmers are always too busy to put their binders on the transport wheels and draw them to the shed. Consequently they are left as near to the shed as is possible to get them without changing the wheels, through rain and weather, until harvesting is finished. A binder costs between £40 and £50, and so it is worth a farmer's while to take special care of it, and so get as much use out of it as he can. To insure a property will cost but a few pounds, while in the case of a fire or the death of a horse the farmer has to stand a heavy loss if uninsured. It is also the wisest plan for the farmer to insure when putting his mares to the horse. This will cost £1 extra, but the foal is worth it; Sore shoulders are a serious trouble, and often cause a lot of waste time in the busy period of the year in washing horses' shoulders, brushing collars, &c. An American horse-driver says he has overcome this difficulty by lining the collar with pure white oilcloth. I have never tried this, but still it may be worth while. With regard to the destruction of rabbits, the only way that this difficulty can be overcome is for the district vermin board to be empowered to give the landholders but a certain time in which to destroy their rabbits, and if the work is not done put men on to do it at the landholders' expense. If this were strictly enforced the country would soon be much freer from the rabbits. The harvesting of the wheat crop is the most important business with which the farmer

has to deal. He must by all means get his crop off and to market as quickly as possible. For the general farmer the complete harvester is the quickest and cheapest machine for reaping, as he has a better chance of getting his wheat marketed before he is caught in a thunderstorm. Professor Lowrie has prophesied that harvesters will not be used 20 years hence. This may be so, but I believe they are the best machines for the farmer, except where he has the good luck to have three or four big boys of his own. If you keep your mind full of ideas about how to farm more successfully, and how to make the family more comfortable, educationally, physically, morally, and financially, you will not have much room for studying meanness or foolishness. It pays to know your trade and know it well. Do not say my farm, my horses, my crop, my cows, but our farm, cows, &c., for the good wife is an equal partner, and as likely as not the more important member of the firm." In discussing the matter, the Hon. Secretary said the only point in favor of harvesters was the saving of labor which they effected. He strongly believed that the use of the stripper and motor winnower was more economical. Mr. J. P. Story said that where the farmer was capable of doing the work, a blacksmith's shop was an excellent addition to the farm. Mr. W. G. Smith thought it advisable to insure stock, but it was not necessary to cover hay or buildings. Mr. Ramsey was not in favor of insuring mares or hay, but thought there was a general tendency to pay too little attention to farm implements. Mr. Searle considered it advisable to insure mares with the owner of the stallion, and the stallion with an insurance society. Mr. R. S. Searle thought the stripper was the most suitable harvesting machine, as the cocky chaff was saved, and this was an important item. In reply to criticisms, Mr. Story said that his experience pointed to the fact that the insurance of mares with the owner of the stallion was advisable. Members generally were of the opinion that steps should be taken to enforce the provisions of the Vermin Act, and it was pointed out that the unoccupied Crown lands in the district were breeding grounds for this pest.

Penong, September 26.

(Average annual rainfall, 12½ in.)

PRESENT.—Messrs. W. Sanders (chair). A. Shipard, W. O. Harris, J. Stiggants, and J. Oats (Hon. Sec.).

SHAREFARMING.—In a paper on this subject, Mr. W. Sanders drew attention to the expense involved on the part of the landholder in providing the necessary stock and implements for sharefarming. During the past year he had entered into agreements with three men, and with horses at £35 a head, wagons at £70, drays £20, ploughs £40, drills £48, strippers £50, winnowers £30, harness £30 and the land costing about 9s. 6d. per acre to clear, the initial costs had been very heavy. In addition to the items mentioned above, it was necessary to provide a horse paddock, housing accommodation, &c. The usual conditions under which sharefarming was carried on in the district were that the proprietor found the whole of the stock, implements, &c., and all material for building, fencing, &c., whilst the other party provided the labor, half the seed, feed, and manure required, and carted all produce to market. In discussing the subject, Mr. A. Shipard said that before undertaking sharefarming it was essential that a careful agreement should be drawn up. Under circumstances where a man was placed on an improved farm, it was generally understood that a portion of the scrub was to be cleared yearly. The owner was expected to find all stock and implements, and in some cases where the shareman was careless there was a good deal of loss in this direction. Mr. W. O. Harris considered that a great deal depended on the character of the person employed. It was folly to put a man without experience on a farm, as there was much expensive stock and implements to be handled. Mr. J. Stiggants expressed the view that the owner should have control of the shareman in a way similar to that which obtained when he employed labor, and in this way direct the work. The Hon. Secretary had for years been working on the share system as follows:—He allowed a certain area to the person living with him, 60 acres in addition to his keep in the case of a single man, and 90 acres and a house where the man was married. The results had been satisfactory, as in a good season the shareman participated in the success, and when the season was unsatisfactory, he helped to bear the loss. He had found that when the above scheme was adopted the men took more interest in their work, endeavored to keep the rabbits down, and took good care of the stock and implements. He had also undertaken the half-share system, himself supplying the stock, implements, half seed, feed, and manure, and the man provided the balance of the seed, &c. Where the season was a good one,

it paid the man fairly well, but if the crop were a failure it would fall heavily on him. When this system was adopted, he believed in the shareman having a say in the management of the farm.

Petina, September 21.

(Average annual rainfall, 12½ in.)

PRESENT.—Messrs. W. Penna (chair), D. T. and J. Kenny, J. H. Wharf, E. and W. Keeley, J. Bascombe, W. G. Lewis, H. Doley (Acting Hon. Sec.), and six visitors.

HOMESTEAD MEETING.—The meeting was held at the homestead of Mr. D. T. Kenny. Several of the members were driven round the wheat paddocks to a patch off which the crop had disappeared. Two hundred acres had been practically cleared, and upon digging about, the ground was found to contain numerous grubs or caterpillars and cocoons. Last year the seed was sown broadcast and ploughed in. This year it was drilled in and sown early.

SHARE FARMING.—Mr. H. Doley read the following paper on this subject:—"A good deal of share farming is carried out in this district, and it can be done very successfully if conducted properly and seasons are fair. It is a means whereby a landholder can use his land to good advantage. The labor problem is not yet solved, so he cannot work as much land as he would like, owing to the lack of competent and reliable men to do the work. When a steady young man is found he offers him a piece of his land to work, and he thus saves himself the worry, and with fair seasons gets good interest for his outlay. The general custom is for the landholder to find the horses, harness, implements, fencing material, and put down tanks, erect sheds and other necessities, and also find half the seed wheat, half the manure, and half the bags, receiving half the crop. The shareman finds the other half of the wheat, manure, bags, &c., and supplies the labor, receiving half the crop. It is a splendid education for a young man to commence farming on these lines, as it gives him an insight into the management of a farm. It is also a good way for a person to get a start where otherwise it would be almost impossible for him to commence farming from weekly earnings. A man should be prepared for worries and drawbacks. He is sure to get them. He needs plenty of energy and pluck. It takes about three seasons to get into proper working order, and there is a good deal of expense and risk. A man starting on the share system should have at least £60. If he can carry on his first year without going into debt it is a great help to him. A good investment is to buy a mare or two for use and also for breeding. In a few years he should have a team of young horses. It also saves driving the horses that are given in with the share contract. It is advisable to have a team consisting of geldings, or mares not intended for breeding. The presence of a number of mares in foal in the team is a great drawback, because when he requires them most they need rest. A percentage of the foals should become the property of the shareman if the mares in the team are allowed to breed, as the foals are a nuisance till after they are weaned. The mares cannot be expected to suckle a foal and do the same work as the other horses. Old and worn out implements and harness are too often given to the shareman. This should not be so, as a man should not be expected to keep in repair harness that has been worn out by others. If given new harness and implements he should keep them in repair and should be able to do the work quicker and better. A blacksmith shop, anvil, and necessary tools should be on every farm. Any small piece of work could be done, and in the busy seasons this would mean a great saving of time. Share farming in the new country blocks is very different from an old-established district. In the new country a man should be entitled to more consideration. He has to make the place, while on the old farm everything is in going order. In this country, where there is a good percentage of plains, a man should start by fallowing, and do as much as possible, as soon as there is sufficient feed. Some crop for hay should be put in, and then he would be sure of feed for seeding operations. The amount of crop should depend on the supply of water at his disposal."

Yallunda, September 21.

PRESENT.—Messrs. Olsten (chair), Forrest, W. Cabot, H. P. Cabot, Fairbrother, Jones, Bryant, Price (Hon. Sec.).

FRUIT-GROWING IN THE DISTRICT.—Mr. S. C. Fairbrother read the following paper on this subject:—"Great care should be taken in selecting a site for a garden, as success or failure largely depends on the class of land chosen. There are hundreds of acres of

land in this district eminently adapted for fruit-growing, and if the farmers were to plant a few trees each year, in time a nice flourishing orchard would be seen on every farm. The class of soil I would suggest for orchards is a deep red loam with red clay subsoil. On most of our sheoak, peppermint, and watergum land patches of this class of soil can be found. Low-lying flat land should be avoided, as this usually becomes very wet and cold during the winter. Most of our soil varies considerably. In one place a good red clay subsoil will be found, and near by it quickly changes to a yellow clay, or there is a deep deposit of gravel between the top soil and the clay. In my orchard the trees on the rising ground, where there is a red clay subsoil, are doing best. This land drains itself better and retains the moisture well during the summer. The position of the orchard is important. It would be a great advantage if protection from the rough westerly winds could be obtained. These do much damage to the trees in the spring and summer. Not only do they knock the trees about, but a good deal of fruit is blown off. The land should be well grubbed and cleared of all stumps, roots, and stones, and should be substantially fenced. Ploughing is the next consideration. If possible, a subsoiler should follow the mouldboard plough. But most of this country contains so many roots that it is a difficult task to use the subsoiler. In view of this, if the land is well ploughed with a good stump-jumping implement, it should be sufficient. It is advisable to dig the holes a month or two before planting the trees, because the soil is then well aerated. I usually dig the holes about 2ft. 6in. square and 15in. to 18in. deep. It is a mistake to sink them too deep in this country, because they will hold the water, and this is injurious to young trees. Twenty feet apart is a good distance to plant the trees in this district. When planting the trees, care should be taken to see that the roots are well distributed around the trunk and that they dip downwards. As the earth is filled in a little well-rotted stable manure should be mixed with it, but do not allow it to touch the roots. The earth should be made firm round the roots and trunk. The trees should be cut back well, as soon as they are planted. I prefer to cut about half the three main limbs away and cut off all small shoots. The land between the trees should be well worked with a cultivator or plough during the spring and a good coating of manure spread around each tree. A good hoeing will also benefit the trees, as it helps to keep the moisture in the soil. Apples and pears do better than any other varieties, and if a careful selection is made of the best export apples and pears, there should be a good living in a 10-acre orchard. We are very free from pests in this district. I have not yet seen the dreaded codlin moth. I have had no occasion to spray the apples or pears for any disease, and I feel confident that really good firm apples which will keep for months, can be grown in this district. I have apples which I picked in April. They have been packed away in a dry place for five months, and are beautifully sound and sweet. The firmer varieties will do better here than the soft varieties, but some of the soft sorts do well. The best kinds for this district are perhaps most of the Pippins, which are good keepers, Jonathans, King David, Cleopatra, Dunns Seedling, and Rome Beauty. With pears, Duchess are easily the best for export and seem to do well. They were selling in London last season up to 25s. per case; Vicar of Winkfield and Winter Nelis also do well. In plums most of the Japanese varieties do well, also Greengage, Orleans, Egg, Golden Drop, Grand Duke, Jefferson, and Prune. Of the apricots early and late Moorpark seem to do best. Peaches—Red May, Highs Canada, Hales Early, Early Crawford, Royal George, Belle of Georgia, Elberta, and Lady Palmerston. Vines also do well, and I am satisfied that we can grow as good grapes here as can be grown in any of the grape-growing districts in South Australia. I find that vines are rather slow in coming into bearing. It seems to take them longer here than in other districts."

EASTERN DISTRICT.

(EAST OF MOUNT LOFTY RANGES.)

Clanfield. September 27.

PRESENT.—Messrs. W. Paull (chair), Pavy, A. Orwell, A. Clutterbuck, H. Milne, A. G. Franklin, L. Gilberton, L. Orwell, A. E. Heaven, A. Corroll, Wm. Queale (Hon. Sec.), and four visitors.

THE CARE OF HAY.—The following paper on this subject was read by Mr. H. Milne:—"It is my intention to deal simply with the treatment and care of the hay after it is cut.

I favor the reaper and binder for cutting the crop. The sheaves should be stooked as soon as possible after being cut, especially if the weather is damp, as the sheaves on the ground will soon sweat and become discolored. I prefer the long, narrow stook made as follows:—Stand one sheaf straight up with two on each side of it at right angles to the row of sheaves and press the heads together. Then stand one sheaf flat on and one on each side of it, the heads slightly lapping. By keeping the butts of the sheaves close in and working both ways from the start the stook may be made any length and contain any number of sheaves, but about 20 to 30 sheaves make a nice stook. The hay will not then be damaged by rain, and it will withstand the wind. The time to cart depends a good deal on the weather, and also the condition in which the crop was cut: but about 12 to 14 days is usually long enough to let it stand. If the weather is hot and dry it can be carted sooner than in showery weather. If the hay is very brittle a good sprinkling with salt water will improve it, and if damp, dry salt will often prevent it going mouldy in the stack. If one has the capital a hay shed will be a paying investment. I have seen little stacks of hay in the hills with four poles and a sliding roof, which is lowered as the hay is used. With a hay shed the stack is safe in course of construction. Many stacks when half or two-thirds built have been pulled down on account of heavy rain, involving much loss of time and damage to the hay. The next best to a hay shed is thatching. Even second rate hay (grass hay or self-sown) will pay for the time and trouble. It is difficult to build a sheaf stack that will turn all the rain. Some builders thatch the stack with the heads of the sheaves while building. This will keep the water out but the grain grows and is spoilt and some of the hay is discolored, which would have all been good feed if the stack had been thatched. In the open it is advisable to have the eaves wider than the bottom of the stack, so that the drips will fall clear from the sides. A good method is to cut some straw with the binder, thus getting the straw straight and in bundles. Two men can thatch a large stack, say 60 to 70 tons, in a couple of days, and it is then safe for the winter." Considerable discussion followed, and the Hon. Secretary raised the question of the right stage for cutting wheaten hay. He believed in cutting as green as possible, because when hay was cut with grain just formed the mice would not trouble the stack as they would if the grain was ripe or nearly so. Mr. Gilbertson preferred to let the hay lie for a day or so before stooking, according to the weather. Mr. Orwell favored cutting when the grain was in the milky stage, as the chaff was sweeter and digested more easily. Mr. Milne said that in stooking hay in the narrow stooks the sooner it was stooked after cutting the better. Oaten hay was best cut when fully ripe. If cut green oats would powder when chaffing. The right stage to cut was when the straw was of a bluish tinge.

Clanfield, October 26.

PRESENT.—Messesrs. A. Richards (chair), A. Orwell, A. Clutterbuck, W. Paull, A. E. Pavy, A. G. Franklin, P. Nelson, J. Nelson, H. Pavy, L. Orwell, A. Heaven, Wm. Qucale (Hon. Sec.), and four visitors.

HARVESTER v. STRIPPER.—Mr. Richards read the following paper:—"The harvester is a combined stripper and winnower, the processes of stripping and cleaning the wheat both going on at the same time. The only stoppage necessary during work is for the purpose of emptying the box; the wheat being then ready for market. This is not the case with the stripper. It has to be driven to the heap and raked out, which entails a loss of time. The wheat from this machine is then cleaned with the winnower. Two men are generally required for winnowing, which involves extra expense and time. The harvester can be started earlier in the morning than is the case with the stripper, and it is possible for a man to take off 250 acres, single handed, with the former. The saving of labor is a most important point." In discussing the subject Mr. Pavy said, in reference to cleaning, that the stripper had a large advantage over the harvester, inasmuch as the outlay for the machine and horseflesh was considerably smaller. The difference in cost of the two implements would pay for a lot of cleaning. Experience over a number of years had shown him that the stripper could be put into the crop many days before the harvester. He had seen the stripper reaping nine days before it was safe to start with the harvester. The upkeep of the harvester was an item of considerable importance. In his opinion the life of that machine was seven years, whereas the life of a stripper was fifteen years. In a very light crop the harvester was very unsatisfactory, and in this case the winnowing was a small item. The loss of time by driving the stripper to the heap was more than made up by the time necessary to drive round the paddock picking

up wheat from the harvester when carting. The danger of fire getting into the stubble must not be overlooked, as there would be very little chance of saving the wheat from the harvester, as it would be scattered all over the place. The simplicity of the stripper was a great point in its favor. It was impossible for a harvester team to keep an even pace all through the harvest, and consequently the sample was sometimes bad. In rough stumpy country it lost a lot of wheat. If the ground were cleared of stumps no doubt the harvester would do better work. Mr. Orwell had seen a lot of wheat wasted over the tail of the winnower and had seen bad samples turned out from the stripper and winnower. The Hon. Secretary said it was practically a necessity for any farmer to keep at least one stripper on hand, because the saving of the cocky chaff was an important factor in new country. He would not advocate saving cocky chaff for the purpose of regularly feeding horses on same, but it was necessary to have something of the sort as a standby in times of shortage. The lightness of the stripper in sandy country was important. The harvester needed considerable attention to keep it in good order, whereas the stripper gave very little trouble.

Forster, September 26.

(Average annual rainfall, 10½ in.)

PRESENT.—Messrs. C. Hayman (chair), T., G., and W. J. Searle, J. Johns, G. and T. Retallack, E. Towill, R. Copp, J. G. Whitfield, C. Payne, W. Sears (Hon. Sec.), and nine visitors.

CONSERVATION OF FODDER.—Mr. C. Payne read the following paper on this subject:—“The farmers in the dry districts of Australia have bought their knowledge during the 1911 season at a very high price. Following a succession of good years the farmers should have had enough fodder reserved to help feed their stock through at least one bad season. Instead of this, on the very commencement of a dry season, they sold their cattle at about one-third of the real value, when a few tons of reserved fodder would have saved them. Farmers generally argue that they cannot afford to cut their crops to feed stock. They fail to realise that they waste the greater part of their crops by not saving the chaff and straw, which make good feed for cattle and young horses. A farmer runs less risk of storms and hot winds shaking the corn out by cutting it in the yellow-ripe stage with the binder and by taking the corn out with the header than by leaving it to get dead ripe for the stripper or harvester. Scientific men tell us that a crop cut in the yellow-ripe stage retains two-thirds of its hay sweetness. When a crop is cut at this period of its development there is enough moisture in the straw to develop the grain, and the sample therefore is just as good as corn that has been allowed to ripen for stripping. A farmer should not cut the whole of a large area with the binder, but he should cut as much as possible when it is in the yellow-ripe stage. To prove the value of the headed straw it is only necessary to compare it with the price of hay chaff during the present season. In this district hundreds of tons of hay chaff have been sold at from £6 to £7 per ton. On this basis it is easy to calculate the value of a fair-sized stack of headed straw if nicely chaffed. It would realise at least a third of the price of the hay chaff. Its value to the farmer, however, is very much greater. The ‘cocky chaff’ from a headed crop is much sweeter and softer than that from a crop which has been ripened for the stripper. The cost of harvesting with a binder and header is not very great, as most farmers keep a binder for cutting their hay crop, and a good header can be bought at a small cost. A large header takes very little motor or horse power to drive it. An important point is to have a good strong wagon or hay trolley and frame to cart it in quickly.” A good deal of discussion followed the reading of the paper, with the opinions in which members generally agreed. This country was considered too rough for binders.

FALLOWING.—Mr. E. Towill stated that with a 1,000 acre farm he would fallow 150 acres each year, and on this put oats. Members generally agreed with this opinion, although some were in favor of fallowing the whole area.

Geranium, October 5.

PRESENT.—Messrs. W. Mitchell (chair), W. J. and I. J. Mitchell, W. and F. Hammond, Jacob, Lang, Lithgow, Dohnt, W. Pannell (Hon. Sec.), and three visitors.

POTATO-GROWING.—Mr. J. Lang read a paper on this subject, in which he mentioned that the potato was one of the oldest vegetables known. It was growing in favor every

year, and the supply must therefore be increased to meet the demand. He thought this district suitable for the growing of potatoes, and would recommend them being planted on sandy loam, as it was the best soil to retain the moisture. All planting should be done in September, unless it was intended to water the plants, when they could be planted later. He would recommend planting Snowflake, Redskin, and White Elephant varieties. The land should be ploughed or grubbed to a depth of 12in., and should be worked to a fine tilth in order to conserve the moisture. Potatoes should be planted in rows 18in. or 20in. apart, and the sets should be 10in. to 14in. apart in the row. He had planted potatoes last year, not from the best seed, but they had turned out very well, some weighing from $\frac{1}{2}$ lb. to 1lb. He would recommend stable manure or bonedust, or would plough in a crop of green stuff, such as peas, beans, or rape. He had seen a good crop of from 5 tons to 7 tons per acre obtained by adopting this practice. Any quantity of water should be given until they began to flower, when watering should be discontinued. A change of seed should be made every two years, and cut sets should be planted with not more than three eyes on each. When planting cut potatoes they should be planted out side downwards. When the potatoes were growing they should be well worked. He would recommend every farmer to try potato-growing, as they would considerably help to decrease the store account. In reply to questions Mr. Lang said that from 3in. to 4in. was the best depth to plant seed. The eyes should in all cases be turned upward in order to allow the shoots to come straight away and avoid the bend that would occur if the eyes were turned downward. In cutting large potatoes for seed two eyes were ample to leave on each piece. If more were left it would result in excess of stalks to the detriment of the tubers. The tail end of a potato was inferior to the front part, and should never be used. The cut surfaces should be dipped in ashes or lime. This would form a skin and prevent drying up or rotting. Stable manure was good as a fertiliser, but if bonedust were used it should be stirred about in the soil and not allowed to come in full contact with the seed. He would harrow potatoes as soon as they were showing above ground. There was no danger of breaking them off and the harrows would keep the surface loose. Where watering was possible planting could take place as late as October, otherwise September was late enough.

Hooper, September 25.

PRESENT.—Messrs. J. R. Beck (chair), G. G. Pitt, J. Boyce, E. G. Colton, C. S. Hall, A. Hood, D. A. Byard (Acting Hon. Sec.), and three visitors.

HARVESTER v. STRIPPER.—The following paper was written by Mr. C. B. R. Wright, and was read by Mr. D. A. Byard :—"The harvester is a great saver of labor, and by using this machine the farmer can take his crop off without assistance. If the weather is at all damp and not suitable for reaping the bags can be sewn in the early mornings. With the harvester there are no heaps of wheat in the paddocks as there are when the stripper is used, and there is then no risk of the wheat being washed away, as it was in the Pinnaroo district a couple of years ago. When the harvester is used the farmer can be carting his wheat while his neighbor, who uses the stripper, is cleaning his crop. This saves a lot of time, and on country which has been cleared well and is free of stumps and large stones, the harvester makes a tip-top sample, as long as the sieves are set properly and are kept clean. The sample is, in fact, good enough for seed. The harvester pays in two ways. First as a time and labor saver, and secondly because the farmer generally clears his land better, in order to work the machine to the best advantage. Taking off a nice even crop with the stripper only requires a boy as driver, whereas the harvester requires an experienced hand to see that everything is working satisfactorily. The main advantage of the stripper is in that it saves the cocky chaff, which, in dry seasons, when hay is scarce and chaff is a big price, comes in very handy and has pulled many a farmer through a bad period. Not only in dry seasons is the chaff an asset, but in any slack time when the horses are not doing much work, cocky chaff and compressed fodder, or a little soaked wheat and pollard, or molasses, makes a good meal and is readily eaten. Some people advocate chaff carriers on the machines, but this practice is only useful when one wishes to save only a few bags. To save any great quantity the stripper cannot be beaten. I prefer the stripper for this district. The little extra which would be paid for cleaning would easily be made up with the chaff. A harvester is of more value on the Adelaide plains, or similar country."

Monarto South, September 28.

PRESENT.—Messrs. G. Patterson (chair), R. E. Anders, J. and H. Frahn, J. and R. Hartmann, B. Hoff, A. Harper, H. Hein, E. Kuchel, R. McDonald, A. Patterson, J. G. H., R., and G. Paech, C. Thiele, E. Tilbrook, C. F. Altmann (Hon. Sec.), and three visitors.

SHEARING.—An interesting address on this subject was delivered by Mr. A. Patterson, in the course of which he stated that the catching pen should always be provided with a grating for the sake of cleanliness. He strongly deprecated the rough handling of sheep by the shearers. Strict supervision was necessary if the farmer would save his sheep from rough treatment and sometimes serious injury. As few second cuts as possible should be made, as these dropped under the wool table and got in with the locks. Broken fleeces should be kept separate from the sound wool, and all stained wool placed together. Cross-bred wool should never be packed with the clip from the Merinos. Even the inclusion of one cross-bred fleece in the bale would affect the price realised. Members generally agreed with the views expressed by Mr. Patterson.

Monarto South, October 26.

PRESENT.—Messrs. G. Patterson (chair), R. E. Anders, H. and B. Frahn, A. P. Braendler, G. Gogol, A., E., and R. Hartmann, A. Harper, E. Kuchel, R. and G. Paech, A. Schenscher, C. Thiele, J. Hutton, E. Tilbrook, G. Thomas, J. Daly, B. Thiele, C. F. Altmann (Hon. Sec.), and five visitors.

HORSE-BREEDING.—In a paper on this subject Mr. A. P. Braendler said that where the farmer desired to have heavy draught horses, it was necessary for him to put stallions of this class to heavy mares. These as a rule were quiet at their work and very good with heavy loads. However, he preferred the medium draught for farm work, as they travelled fast and stood longer journeys daily. In addition, there was not so much risk with the mares at foaling time. Mares could be worked if well fed and carefully handled up to within a month of foaling time. After foaling they should be well fed and rested. The foals should be weaned after reaching the age of four or five months, and then should have an abundance of feed and water. In discussing the subject, Mr. Anders was of the opinion that farmers generally paid insufficient attention to the selection of their stallions. They should only breed from the heaviest draught horses. The majority of members, however, were in favor of the medium-sized draught of the heavy trolly type.

Morgan, September 28.

(Average annual rainfall, 9in.)

PRESENT.—Messrs. R. Wohling (chair), E. Hausler, E. French, R. Wohling, jun., E. Gilgen, O. Hausler, I. Pope, J. T. Hempel, H. Wohling (Hon. Sec.).

POULTRY-KEEPING.—Mr. O. Hausler read a paper on this subject. In this district, he said, hatching should be over by the middle of October. In the hills and other late districts it could be continued to the end of October, but chicks hatched later than that were seldom as profitable as the earlier ones. Late birds did not commence to lay until eggs were cheap, the birds did not mature so quickly, they were not so robust or resistant to disease, and in the case of table birds, whether ducks, turkeys, or fowls, the early birds were ready for the best market. It also cost more to fatten late-hatched chicks and ducklings. The practice of keeping mongrels was unprofitable. It would pay everyone to secure some eggs from recognised breeds of reliable laying strains, particularly those whose birds had been successful in the Roseworthy Competitions. He thought it better to get the eggs than to buy the chicks, as the losses were less when the chicks were under the care of the hen that hatched them. In the discussion which followed, Mr. French thought it advisable to get a fresh rooster in the yard from time to time to introduce new blood. Mr. E. Hausler had had good success with a sitting of first-class eggs last season. Mr. Gilgen advocated chaffed lucerne as a food for fowls. Mr. O. Wohling thought August was the best month to set hens in this district.

Parilla Well, September 26.

PRESENT.—Messrs. J. E. Johnston (chair), J. W. Johnston, J. T. Johnston, F. C. and A. Webster, E. H. and H. Leak, B. Jackel, B. Pahl, F. and A. Nordhausten, J. Flavel, W. Flavel, J. Ferguson, L. G. Neville (Hon. Sec.) and one visitor.

FARM HORSES.—Messrs. F. C. and A. Webster contributed the following paper:—
 “Our district consists principally of sandy soil that is moderately easily worked, and in fair seasons there is abundance of green feed in the paddocks. In describing a horse suitable for this locality, we recognise that it must be one that will breed true to type. Irrespective of breeding, the horse should be what we term a good doer and a fair traveller. These qualities are usually found in an animal possessing the following characteristics:—Compact build, round barrel, well ribbed up, short back, good sloping shoulders, wide and strong across the loins, broad deep chest, moderate to short legs, clean strong joints, with plenty of well-developed muscle. We favor the medium draught, that is a size or two below our very heavy draughts. They thrive on less feed than the heavy animals, and as a rule travel much faster. In nine cases out of 10 the smaller horse will be found in the lead of a team with the heavy ones back in the body. It is easier to breed a medium draught true to standard than it is to breed a heavy draught. The majority of the heavy draughts are loosely built and have a tendency to slab sides and a long back. They are not fast movers and their own weight is often a burden to them. The most profitable foal is bred by a draught mare, should the owner wish to sell, that is, considering the price obtained for the foal only; but the price obtained for the foal is not the only consideration. For breeding foals for sale we favor mating the medium mares to a heavy draught stallion. It will be found that they will travel with greater ease while carrying the foal and will work nearer to the time of foaling than the heavy mares. Care should be taken in selecting a sire. Farmers should not patronise cheap or convenient horses. The most useful beast for all-round farm work and the most favorable to the majority of farmers is the medium Clydesdale. The brood mares, when near to foaling, should receive very careful attention, and should be kept in a paddock by themselves when expected to foal, and not allowed to roam among other loose horses. It is advisable to watch mares at any time when near foaling, especially during the night. Very often both the foal and mare die for the want of assistance when in the act of foaling. In these cases owners only have themselves to blame, as the trouble is brought on them through their own neglect. We advocate working brood mares well up to the time of foaling, provided they are in fair condition, in order to give them plenty of exercise and keep them from becoming too fat, as such is often injurious to the mare when foaling. The foal should be watched to see that it sucks properly and then turned out in a paddock where feed is plentiful. It is best to avoid working the mare while she is suckling the foal, which should be six months old before weaning. When being weaned it should be taken out of sight of the mother till she has dried off. A foal should be kept from its mother till she is properly dried off. If horses from five years old are fed well, they will comfortably do 10 hours' work or even more in the busy time of the year, such as harvesting; and eight hours will be found long enough through the winter months, as the work is usually wet and heavy. From two to three years old is the right age at which to break in young horses. Horses broken in at two years will be found none the worse for doing a little work so long as they are worked lightly. Coolness of temper and patience is needed when breaking horses. They should be carefully handled, the use of the whip should be avoided. They should be taken quietly and treated kindly. We do not believe in spending three or four days in handling a young horse, mouthing it up and letting it run about the yard with a bridle, reins, surcingle, and such like. Place it in the team among fairly reliable horses as soon as possible. We advocate working horses on one-horse swingle-bars in preference to spreaders. Both are used nowadays a good deal, and we find the swingle-bars are not so likely to cause the horses sore shoulders, as they put equal weight on the shoulders. It is advisable to have all chains of equal length. In working eight horses in a team or a plough or any such implement, place them all abreast. Thus each horse does its own share of the work. With leaders, one generally loads on the other. Horses should be groomed well at least once a day, and their shoulders should be always clean and free from dry sweat and dirt. Care should be taken to get a collar to fit the horse. Another important point is to see that the hames fit the collar, as a good many sets of hames made at present have the draught too low down, and most of the pressure comes on the points of the horses' shoulders instead of being distributed. It is a mistake to use a collar too large for the horse. It should always fit close in against the animal's neck. Bathe horses', especially young animals', shoulders with cold water after they have done their day's work in harvest time. This keeps them from scalding. Farmers should have their horses' collars lined and stuffed at least

once a year, and any horse that is subject to sore shoulders should have its collar eased where the sore touches. A good plan is to cut a small hole in the lining and remove the stuffing, and so prevent the collar touching the sore. A good warm roomy stable is best, and do not tie the horses up unless necessary, as this does not give them an opportunity to rest with comfort. Always feed with good sound food. Chaff should be cut at least a half inch in length and not powdered up into dust. This is the most beneficial feed, especially for aged horses, as they often have a tendency to bite off the heads of long hay, and the rest is practically wasted. One feed of long hay each day would not be amiss, especially late in the evening. The animal would then have ample time to chew its food with content. Long hay is also beneficial to the animal's teeth, as it prevents them wearing too flat. A little oats or other corn should be added to the feed at each meal. Too much is not good, as it may cause sores to break out on the shoulders. Oats is usually preferred for mixing with chaff." In discussing the subject Mr. J. S. Ferguson expressed the view that it was desirable when working teams of six horses or over to split the team up and work with leaders. He had tried feeding with long hay, and his experience was that horses could not be kept in good condition on this ration. Mr. E. H. Leak had found the use of a backband had the effect of reducing a number of cases of sore shoulders. Mr. J. E. Johnston preferred working brood mares right up to the time of foaling. He would not feed with long hay, as he considered this wasteful. Mr. L. G. Neville preferred the heavy horses for farm work. If the animal had not weight to put into the collar, it was necessary for it to use muscle, consequently the lighter horse fell away from condition more quickly. Oaten hay chaff was best for feeding horses, as it contained a good deal of grain, which was particularly suited to building up the strength of the horses. The feeding of long hay was wasteful, and in addition there was a tendency for the animals thus fed to become infested with worms through treading the hay under foot and then picking it up.

Pinnaroo, October 19.

PRESENT.—Messrs. B. L. Harfield (chair), M. Beckwith, J. Docking, H. E. Dibben, F. H. Edwards, G. Fuller, L. M. Ferguson, H. J. Harfield, F. Hunt, H. C. Hill, W. H. Kelly, H. Ledger, C. Lee, M. McCabe, B. H. Nash, E. H. Parsons, A. I. Reed, C. A. E. Schiller, L. Small, W. Venning, P. H. Jones (Hon. Sec.), and two visitors.

CAPILLARITY.—Mr. E. H. Parsons, A.S.A.S.M., contributed the following paper:—"This subject may be conveniently divided into three headings: (a) What is capillarity? (b) How does it affect our soils? (c) How is it to be controlled and used? Capillarity is the name given to a distinct physical phenomenon, which is easier to demonstrate than describe. If a thin glass tube, open at both ends, has one end immersed in water or any other liquid, the liquid will rise higher in the tube than the level of the liquid surrounding the tube. Liquids will rise naturally in microscopic tubes to a considerable height. The question now is: How does this physical phenomenon affect farmers? When rain falls it soaks downwards and in doing so forms millions of microscopic tubes or channels in the ground. As soon as the sun's heat dries the surface the moisture rises through these tubes to keep the surface damp. Sand, owing to its open nature, does not lend itself readily to the formation of capillary channels; hence the fact that sand will retain its moisture so very much longer than other ground. Of course, at present I am speaking of Pinnaroo sand, which is really a sandy loam over clay. If there were no clay bottom the moisture would soak away through the sand, but it is wonderful how long bottomless sand even will keep damp, owing to the comparative absence of these capillary tubes. The next question is: How can we control capillarity? The best way is by ploughing. The more open the surface is kept the less chance is there of forming capillary tubes. The whole secret of fallow retaining moisture is in this fact. The moisture from the winter rains soaks down into the ground, and in doing so forms millions of these microscopic tubes. When we fallow we break these tubes and imprison the moisture. But we must not stop at that. Each time rain falls a fresh lot of tubes are formed, although until the ground sets not to anything like the same extent as in virgin soil. To make fallow thoroughly effective these capillary tubes must be broken every time they are formed, i.e., after every rain. It must be borne in mind that the capillary tubes formed by a subsequent rain will let out the moisture conserved from a former rain. To put this a little plainer: If after the land is fallowed and harrowed, rain again falls after the harrowing and forms capillary tubes, these tubes will let out not only the moisture from the rain after the fallowing but also the moisture conserved by the original

fallowing. By this you will see clearly that it is only by continuously keeping the surface broken after all rains, by harrowing or any other means, that the loss of moisture from capillarity can be minimised and the best effects of fallowing, or retaining moisture in the ground, be obtained." Mr. McCabe remarked that whilst it was advisable to keep the top soil loose the harrowing or cultivating should always be done when the ground was wet. Working fallow in a dry state only increased the risk of takeall.

WHEAT-GROWING COMPETITION.—In conjunction with the Parilla Well Branch it was decided to start a competition for the purpose of securing pedigree wheat, and also improving the standard of the grain.

HORSE AILMENTS.—A member sought information concerning a form of grub which had been passed with the dung by one of his animals. Members were unanimous in the opinion that it was a bot, and the owner was recommended to drench his horse with 4ozs. or 5ozs. gall, subsequent to starving the animal for 24 hours, and then follow two hours later with a strong purgative.

Renmark, September 24.

(Average annual rainfall, 11in.)

PRESENT.—Messrs. W. H. Waters (chair), H. DeWitt, J. S. Huggins, A. Braund, F. Cole, C. J. Everard (Hon. Sec.), and two visitors.

SULPHURING APRICOTS.—Mr. DeWitt reported that as the result of some experiments he had conducted he had found that if the temperature of the sulphur house were kept at about 50°C. only half the quantity of sulphur was would be required to obtain the same result as was needed if a lower temperature prevailed. Mr. F. Cole had secured better results from the use of a pug sulphur house than from one made of hessian. Some ventilation was necessary to make the sulphur burn properly. It was agreed by those present that dried apricots made better jam than fresh ones. Mr. A. Braund thought the best jam could be made from the green fruit.

Renmark, October 22.

(Average annual rainfall, 11in.)

PRESENT.—Messrs. W. H. Waters (chair), H. DeWitt, E. Cole, H. S. Taylor, M. B. Geneste, C. J. Everard (Hon. Sec.).

DAIRYING AND FRUIT-GROWING.—Mr. Taylor suggested that fruit-growing could be profitably combined with dairying on the settlements adjacent to the Murray. Members generally regarded this as impracticable, as the majority of the growers of fruit would be unable to spend time in milking during the fruit season. Mr. Waters had kept three cows on three acres of paspalum during the summer. He sowed the seed in June, but the grass did not show up until the following February. On two acres of phalaris commutata grass he had kept four cows through the winter. Mr. Taylor thought lucerne was certainly the best fodder to grow under irrigation, and at Mildura there were a number of crops grown on 20-year old plants. The blocks had never been fed off.

Tintinara, September 28.

PRESENT.—Messrs. R. J. Gully (chair), C. M. Ives, G. Ives, D. N. and J. Bell, A. J. Bryden, D. T. Kennedy, T. Stead, W. J. Marshall, E. B. Northcott, J. Helling, D. McKeand, C. P. Hodge (Acting Hon. Sec.), and one visitor.

CULTIVATION OF THE SOIL.—Mr. C. P. Hodge contributed the following paper:—"Before dealing with the actual cultivation of the soil, I think it might be advisable to make a few remarks in reference to the preparation of the land before ploughing. To my mind the success or failure of the crop depends almost as much on the work done before cultivation starts as the actual cultivation itself. In this class of country it is of the utmost importance to get a good scrub burn. In fact, I deem it of such importance that I would strongly recommend anyone to leave a piece of land one or even two years longer, rather than plough it up without first burning the rubbish off it. Of course, there may be occasions when circumstances make it impossible to adhere to this rule. For example, a man may settle on a block of land here and find there is none of it in a fit state to carry a fire. Then, of course, he must make the best of a bad job and plough through the

rubbish. But where possible I feel certain that to obtain a fire before starting cultivation may safely be regarded as an excellent rule to follow. To ensure a good burn if the land be mallee, it should all be logged or rolled down, and, if possible, all springbacks cut. The same applies to heath country, for there is always sufficient dwarf oak, honey-suckle, &c., to pay for the time of knocking them down with a log. Where gum trees are encountered they should be mullinised level with the ground. Whether one secures a good burn or not, I would recommend the same practice in both instances, that is, to fallow the land well before attempting to put it under crop. I would even suggest this practice to the new settler. Of course, he must put in a little the first year, but let it be a little well put in, so that he may have a chance of cutting hay for himself for the following year. I should recommend that he only attempts to put in 100 acres during the first year and devote the rest of his time to fallowing for the following year. I am confident that he will be money in pocket by following such a policy, instead of trying to get a large area under crop straight away. The next point to consider is the time to fallow. This should be done as soon after seeding as possible. June and July, under normal conditions, are the best months in which to fallow here, for the ground is thoroughly wet, which enables the plough to do good work, as well as get rid of many more stumps and yaccas than would be the case if left till later when the ground is drier. By fallowing early the ground is left open to receive the heavy winter rain, which after all is one of the main factors of fallowing. The depth is a question which must largely depend on the nature of the country in which one is working. The soil is so variable that it would be impossible to lay down a hard and fast rule as to depth. For instance, in the sandy heath country, where one has so many yaccas with which to contend, I would recommend ploughing as deep as is necessary to plough out the majority of the yaccas. In the more firm mallee and gum land, I would suggest 4in. as a rough guide to the general depth, though this will necessarily vary with the nature of the land. Don't try to make the ploughing too smooth. In my opinion the rougher it is the better. I would rather see ploughing ridged here, than turned right over and left too level on top. If left too level the air and sun do not get into it sufficiently to sweeten it. Then, too, if left level the rain beats it down and it sets too hard to work up well. I recommend leaving the fallow rough, without even harrowing, until October, by which time most of the heavy rain will be over. Then I would harrow it. Do not work fallow deeply at all. Harrow again after each rain when practicable. In this way the surface is kept loose without the damp soil underneath being exposed to evaporation. This brings us on to seeding. In the case of fallow I would recommend working the land with the disc cultivator to a depth of about 3in. after the first heavy rains have fallen. Then harrow down in front of the drill. Where it is possible to cover the seed without harrowing behind the drill I would advise doing so, as I think it a mistake to leave the land too smooth. Where one must harrow after the drill to cover the seed I would not use this implement before the drill. I would rather see a little seed uncovered than harrow behind the drill. In the case of stubble land I would advise ploughing. Never put a crop in with the cultivator. If one has not time to work it up with the plough put in half the quantity intended, and leave the balance to fallow for the coming season. My objection to the cultivator as a means of working up stubble land is that there are always hard patches in this country that have not been properly ploughed the year before, consequently if one puts the cultivator into the land one is simply scratching over the surface of these hard patches again, instead of breaking them up well as would be the case with the plough. In conclusion, as a general principle, I would advise putting in a smaller quantity, but putting it in well, and where possible, let the bulk of the crop be put on fallow land, and I feel sure the present returns from this district will be nearly doubled. The sooner the land is ploughed and left rough the longer the sun and air have to penetrate it. This is an important matter, for air and sunlight are necessary for the life of the bacteria whose function it is to carry on the nitrification whereby the fertility of the soil is maintained. As to the best plough for fallowing, I would suggest that a disc plough be used for the first breaking up, to cut through the fibrous matter, and after that I would advise a good strong share plough."

CARE OF LIVESTOCK.—This subject was dealt with in a paper by Mr. N. Bell, reading as follows:—"The working stock on the farm should be our first consideration. They should be well housed and cared for in every possible way. For a climate such as we have here, I favor a stable closed in all around with large sliding doors, leaving all horses loose. Many farmers favor tying up or stalling them, but should fire occur a great risk is run, horses being as a rule awkward to get out. Much time would be lost in unfastening ropes or removing the animals from the stalls. Too much care cannot be given to the feeding and watering of horses. In a district similar to this feed is one of the farmer's biggest items, and most of us are endeavoring to get as much work out of our horses on as little

feed as possible. I favor giving an average working horse in three feeds, say, a daily ration of 20lbs. to 25lbs. of good chaff damped with molasses, which should always be fed where grass is at all scarce, to ensure health. Then a small quantity of oats, bran, or pollard can be added. Should oats be used 10lbs. a day would be found sufficient. When bran or pollard are fed, give, say 5lbs. of each. For sandy country I prefer the latter. A feed of two sheaves of hay should also be given at night. Horses should receive their meals at regular intervals if possible. When the farmer's work takes him any distance from the home, it is a good idea to nosebag at mid-day instead of unharnessing and travelling to dinner, as every little distance travelled helps to tire the team, and in winter a horse will go from morning until night without a drink. Of course, if water can be taken into the paddock so much the better. When the above plan is adopted great care should be taken not to let horses take too much water on coming in at night, especially if they are at all hot. For this reason I would prefer water outside of the yard. Another very important point with reference to the working horse is the attention to its shoulders. As many of us know, it is a very difficult matter to keep horses from galling in stumpy country, especially when corn is being fed at all heavily. Horses should never be harnessed without the shoulders being well brushed, and every trace of sweat, &c., thoroughly cleaned off. Too much time cannot be spent in fitting the collar. This is the most important factor of all, as should it be at all wide and bear on the shoulder-blades a gall will result. After the horse has been properly fitted with a collar the position for the draught should be well considered. Greasing shoulders when collars are removed at night, to my mind, is a mistake, as this method helps to accumulate the sand should the animal roll or lie down. I have found boracic acid sprinkled on the gall helps to heal the wound better than other treatments. The wound should be damped before the application is made. Dry black lead powdered and rubbed on the collar to come in contact with the affected part when horses are harnessed is beneficial. The latter treatment helps to work a face on the sore. The dairy cows should have particular attention if profitable returns are sought, and one of the most important items is proper housing. On most farms dairy cows are turned adrift and compelled to pick their own living; this is a great mistake, especially in scrub country, as the natural herbage is not a good butter producer. Cows should also be well fed, the feed including a little bran until sufficient grass is available. Should the weather be at all rough or stormy cows are better housed and stalled, the stalls being kept thoroughly clean. Many dairy cows are ruined through not being milked dry. Salt and bonemeal are two very necessary articles to ensure good health in our dairy herds, and boxes should be placed in convenient positions about the yards so that all stock may obtain any quantity they require. We would all do well to bear in mind the fact that it always pays to keep the best and most suitable stock, and the property on which they are running should not be overstocked."

Tintinara, October 26.

PRESENT.—Messrs. R. J. Gully (chair), D. A. and J. Bell, J. Donaldson, R. L. and L. M. Scott, N. and G. Bainger, D. T. Kennedy, D. McKeand, C. M. Ives, A. K. Wendt, B. G. and H. C. Filman, R. Henderson, and C. P. Hodge (Acting Hon. Sec.).

HANDLING YOUNG HORSES.—This subject was dealt with by Mr. C. M. Ives in the following paper:—"Young horses have different dispositions. They cannot all be handled in the same way, but must be treated with firmness and kindness. A horse has a good memory, and the first thing taught him, good or bad, has a decided influence over him. A timid horse must at all times be approached gently, giving it time to remember its previous lessons. When handling a young horse, if I see that he is losing his temper, or I feel like losing mine, I always get out of the yard for a while. To catch and handle a wild unbroken colt, I prefer a round yard about 21ft. in diameter. This is made from 10 posts about 11ft. long and 40 rails 6½ft. long. After running the colt into the yard, I allow him to stand for a few minutes, and when sufficiently cooled down, I take a light stick with a handkerchief or rag tied to the end and go quietly into the yard and stand still until the colt gets used to me. I then gently wave the stick and rag first in front of the colt and then behind, endeavoring to keep the animal as much as possible in the same part of the yard all the time and never letting him pass me. The colt will soon stand still and smell the rag and even allow it to pass along his back. I then gradually work closer, keeping my eyes on the horse's eyes all the time and rubbing his back and neck with the stick. By this time the colt will stand and allow itself to be stroked by hand, first on the shoulder and then gradually up its neck, round its ears,

and down its nose. A leather halter or headstall must now be put on. I first hold it for the colt to smell and then rub it on its shoulder, gradually working it up his neck until I can gently slip it over his ears. I then quietly buckle the throat and chin straps. I next take a long rein or light rope about 18ft. long and lunge the horse, but do not put a bit in its mouth. A colt should always be taught that he can be held and tied up before a bit is placed in his mouth. Do not haul on a horse's mouth and make it sore. If you do the horse is almost sure to develop a hard and uneven mouth. Mouthing is all education, and it is possible to teach a horse to guide anywhere by a band round the nose to which reins are attached just as well and perhaps better than if the bit is used. I use the rein on the headstall to keep the colt's head towards me while I rub him down on both sides and teach him to stand. The roller and crupper have to be put on next. I allow the colt to smell the roller, then rub him down with it, put it on his back, and with a short piece of wire with a hook at the end I reach under his belly and pull the buckle or ring at the end of the roller towards me so that I can buckle it without the risk of being kicked. Before putting the crupper on I generally strap up the colt's near front foot with a stirrup leather. When the colt is accustomed to standing on three legs, I pull his head round and hold the rein and his tail in my left hand while I put the crupper on with my right. Do not do the crupper up too tight, for if the horse becomes sore under the tail, he is almost sure to buck when ridden with a crupper. It generally takes from 10 to 30 minutes to put all the tackling on a station colt without roping him or putting him in a crush pen, but I have never found two alike. A wild colt that nearly goes mad with fright when a man first goes in a yard with him is generally very easy to handle once a hand is placed on him. A slow cunning colt is more likely to give trouble. If I have a vicious colt that comes at me with his heels the first time I get in a yard with him, I put a quiet old horse in the yard and keep him between the colt and myself as much as possible until I have the headstall and leading rein on. When I have the tackling on I generally let the colt have a rest for a few minutes. I then rub him down, throw bags on him, pick his feet up, jump up and down on the ground alongside of him and lean my weight over his back. After that I tie him up to a post, using a sound chaff bag and a good piece of ½ in. rope. I place the chaff bag folded lengthwise round the colt's neck and pass a piece of rope through the noseband under the chin and tie to the bag with two half-hitches. When the rope is attached to the bag round his neck I tie it to a strong post, but do not give him more than 4ft. of rope, for if the colt has too much play it is possible for him to break his neck. I generally put at the same time a light rope over his rump, like a breeching, so that if he hangs back too much I can give it a pull and make him stand up. After the colt has learnt to stand when I run up to him or throw bags on him, I teach him to lead. If a boy is handy get him to follow behind with a whip, but if there is no help, put a light rope or clothes line through the noseband of the headstall, then over his back round behind him like a breeching, once more over his back, and then tie the end with a bowline knot to the rope under his jaws. After I have taught the colt to lead, I put a bit in his mouth and some long reins on him and drive him round a large yard, first to the right then to the left, but not letting him go out of a walk. When he has learnt that lesson and does not try to get away, I drive him up and down the middle of the yard and turn him in all directions, teaching him to walk, trot, stop, and move on again, taking care not to jerk his mouth or do anything to make it sore. When I have him well under control and can walk and trot him and turn when and where I please, I put a saddle on him in the small yard and mount and dismount a few dozen times in as many different ways as I can think of doing it. If he does not stand, I hobble him or strap up his near front leg until he will stand. I next take him out in the large yard and ride him round, stopping frequently and getting on and off. After that I ride him out in the open, but generally get a man or boy to come with me on a quiet horse. The following day, if I wish to break the colt into harness, I ride him near a buggy for a mile or so and then tie the colt to the off-side buggy horse and drive about until he becomes accustomed to the noise of the trap. I then quickly take out the off-side buggy horse and put the colt in his place, but still keep the open bridle on the youngster. Start the pair off at a trot, and when the colt has settled down teach him to walk and stop and start again. Do not give a young horse too much work at first, for once knocked up he will never be the same horse again. A quiet farm-bred draught colt does not need so much handling as a station colt that never sees a stable, but I should teach him to lead and tie up in the same way. I should also mouth him and teach him to guide with the long reins in a big yard. I generally hitch draught colts to a very light log and teach them to turn in all directions, stop and go on again by word of command as much as possible. After that I hook them on to rather a heavier

log, but never ask them to pull as much as they are able to. It is then a good plan to put them into a wagon team on a good road, or where there is not much to pull. After that they should be tried at all kinds of work, but I do not ask them to do as much as old horses or horses that are accustomed to the work."

Wilkawatt, September 28.

PRESENT.—Messrs. J. Ivett (chair), W. J., D. F., and D. Bowman, T. and C. Sorrell, T. Sorrell, sen., J. W., G. A., and F. W. Altus, E. W. and H. H. Brooker, A. V. Ivett, A. J. McAvaney, B. Spackman, W. R. and M. Neville, J. P. O'Shea, M. Hayes, F. W. Gasmier, H. H. Pritchard, B. Tylor, P. Rigney, W. J. Tylor (Hon. Sec), and three visitors.

CLEARING BURNT SCRUB.—Mr. F. W. Altus read a paper on this subject, in which he advocated rolling burnt scrub just before harvest, as the scrub was then drier and would break better. It was then advisable to wait until after harvest before cutting the bushes, as they would have time to dry and it could be seen what needed cutting. If the bushes were cut a fortnight or three weeks before burning they gave more heat when burnt than if cut in the winter and the wind and rain were allowed to beat them flat on the ground. He would burn on a day when a good north wind was blowing. After burning he would rake all remaining sticks into heaps with a horse rake before the wind buried them with sand. Members generally agreed with the paper.

LUCERNE.—Mr. M. Neville read the following paper on this subject:—"The land intended for lucerne-growing should be fallowed as early as possible, and the stumps not pulled out by the plough should be grubbed out. The land should be thoroughly cleared and cultivated after a good rain, leaving it fairly rough. Enough stable manure to put a layer about 3in. thick on the land should be carted before ploughing the following season. The manure should be left in heaps to rot, as well-rotted manure is much better for ploughing in, and also has a more forcing effect on plant life than fresh manure. I would also cart enough for mulching purposes later on. Early in July the following year spread the manure and plough it in, sow a liberal quantity of bone manure or super., say from 1cwt. to 2cwts. per acre, and harrow it in. At the end of July broadcast about 60lbs. of wheat per acre and harrow the land till it has a fairly fine tilth. The wheat will protect the lucerne from frost later on. It would be advisable at that time to put a rabbit-proof fence round the plot, which would also keep fowls away from the seed. When the surface of the soil is fairly dry, harrow lightly and broadcast about 10lbs. of lucerne seed to the acre, and just slightly cover it. Hunter River lucerne is a very good variety to grow. It grows rapidly and is very hardy. When the crop has reached a height of about 6in. it is a good plan to cut it and let it lie on the ground, as it acts as a mulch to keep the surface of the ground moist, besides giving the crop a fresh start. The second growth will be more vigorous than the first, and should be cut when coming into flower, as lucerne is most nourishing at that stage. As soon as the second growth is cut the surface of the land should be worked moderately and a mulch of well-rotted stable manure about 2in. thick applied, which will keep the surface free and moist. This should be sufficient working and manuring for the first season. After the last crop for the season has been removed mulch with manure and leave it to winter. In early spring harrow thoroughly. This will give the crop a good start, and make it grow much thicker, because when lucerne is established the more it is knocked about after cutting the thicker it will grow. A good harrowing after each cut should be sufficient without manure to grow a good crop through the season. At the end of the season repeat the mulching and leave to winter. This method can be carried on from year to year and good results should be obtained. If at any time the crop is backward in its growth a dressing of bone manure will have a wonderful effect. Lucerne should be watered three or four days before cutting, as the watering makes it more succulent and the new growth comes straight away. I think that one watering besides this (in the growing period) would be enough for this district. Lucerne should be left at least 12 hours to wilt after cutting before being fed to stock, as otherwise they are liable to become blown. When cutting the lucerne do not cut off the crown of the plant, and never let the plant go to seed, because this is weakening to the plant itself, and the cut is of little value as a fodder at that stage."

SOUTH AND HILLS DISTRICT.

Cherry Gardens, September 24.

(Average annual rainfall, 35.3in.)

PRESENT.—Messrs. S. W. Chapman (chair), T. Jacobs, A. Broadbent, C. Rioks, C. Lewis, J. Lewis, J. Tozer, E. Broadbent, H. Jacobs, A. Jacobs, H. Lewis, T. Jacobs, jun., S. H. Curnow (Hon. Sec.).

CULTIVATION OF ROOT CROPS.—Mr. A. Jacobs read a paper under this heading. The relatively low prices frequently prevailing for root vegetables sometimes led the grower to treat their production in a haphazard manner. He thought, however, that if worth growing at all it would pay the gardener to get them as nearly perfect as possible. The soil should be in good heart, a condition secured by judicious manuring and adequate cultivation. Virgin soil would not produce good root crops unless the ground had been broken to a good depth before the preceding summer to allow sun and air to sweeten it. The land should be scarified several times towards the end of summer, preferably after rain. He would spread a good dressing of farmyard manure over the surface and leave it till planting time, when it should be dug in deeply and worked well into the soil. Root crops would thrive in the fine tilth thus produced. Mangolds, a splendid fodder for milch cows, should be planted in rich soil deeply cultivated, put in drills about 2in. deep, with the rows 2ft. apart. The plants should later be thinned out to about 9in. or a foot apart. Early in September was a good time to plant in this district. Beetroots required much the same treatment, but the distance between the rows and plants might be reduced by half and the seed planted 1in. deep. To make turnips and swedes grow quickly they also should be put in an even seedbed, in drills an inch deep, with the rows 10in. apart. They should be thinned out, leaving 4in. between the plants. He found it advisable to sow finely-rolled sulphate of ammonia over them at the rate of about 4lbs. to the rod. He would irrigate immediately, and in about three weeks time repeat the procedure. If irrigation were not practicable it was better not to force the growth. Potatoes should be put in good soil 4in. deep, and it was advisable to scarify the ground, if the surface were dry enough, just as the shoots came through. With all these crops, and many others, the hoe should be well used as soon as the plants were up, and continued until there was danger of damaging the top or root. Members were generally in agreement with the paper. Mr. T. Jacobs thought that land should be manured the year before parsnips or carrots were planted. Mr. Lewis said that only well-rotted stable manure should be used for these two crops, as new manure caused forks in the roots.

Hartley, September 25.

(Average annual rainfall, 16in.)

PRESENT.—Messrs. B. Wundersitz (chair), J. F. Tydeman, D. Clark, W. Brook, W. Bermingham, T. Phillips, G. Phillips, S. Pratt, G. Hill, J. M. Hudd, F. Burns, W. T. Richardson, M. Hassam, J. Stanton (Hon. Sec.), and 20 visitors.

HOMESTEAD MEETING.—This meeting was held at the residence of Mr. J. M. Hudd. Upon inspecting the crops, the visitors considered they looked very well, considering the lateness of the season. With favorable spring showers there was every prospect of fair results. Some White Garton oats appeared to be rather roedy and inclined to run up, while the Black Cartons kept more to the ground, and looked the more promising of the two. The principal oat crop was of the Calcutta variety. A mixture of Glyvas and Comeback wheats made the best crop on the farm. The peas also looked very well. The evening was spent with music and other items, and at the conclusion Mr. and Mrs. Hudd were cordially thanked for their hospitality.

Ironbank, October 25.

PRESENT.—Messrs. C. Morgan (chair), W. Dalton, E. Coats, R. Coats, N. Coats, S. D. Evans, A. I. Coats, F. Brown, L. Ahrens, J. Morgan, W. Coats (Hon. Sec.), and two visitors.

UTILISATION OF WASTE LAND.—In a paper on this subject the Hon. Secretary said that where they had land that was of poor quality, it could be utilised by first selecting

the trees that would be suitable for fencing, building, &c., and ringbarking these, then proceeding to cut the undergrowth out by the roots, and leaving it on the ground for a period of about 12 months to decay. This would improve the nature of the surface soil, and wattles could be sown. Stones should be gathered and heaped until such time as they might be required for walls, &c. Where the soil was of good quality, it could be carted to poorer spots, the pits being filled up to within 12in. or 15in. of the surface with stones, which should be covered with earth. The ringbarked trees would be ready for removal during the next winter. It would be found that this would improve the texture of the soil, and the land could be utilised for grazing, gardening, or for growing timber. The writer did not believe in allowing a fire to go over the land. In discussing the subject, Mr. F. Brown considered that a scrub burn was good for the soil, and Mr. T. Jacobs agreed. Members were generally divided in opinion on this point.

Kingscote, October 7.

(Average annual rainfall, 18½in.)

PRESENT.—Messrs. J. Turner (chair), P. T. Bell, J. Wright, K. Nash, F. W. Jacká, S. H. Anderson, M. J. Chigwin, J. Codling, V. H. F. Cook (Hon. Sec.), and one visitor.

MIXED FARMING.—Mr. J. Turner contributed a paper on this subject. Every farm of about 500 acres of fair average land in this district, he said, should be conducted on a system of mixed farming, such as keeping a few sheep and cows, about 150 to 200 fowls, and the necessary horses for working the farm. About four draught horses and one or two saddle or trap hacks should suffice. The sheep would provide fresh meat for household use, and the skins and wool would yield a small income. All the butter for home consumption would be supplied from the cows, and there would probably be a surplus for sale. The fowls should supply all the eggs necessary, and would also be a source of income. By judicious management the profits from the sheep, cows, and fowls would be sufficient to pay the storekeeper's and miller's accounts for 12 months. Every farmer should grow his own vegetables on the farm. This would save many journeys to the township for fresh supplies. Each journey entailed the loss of probably half a day, and he had calculated that 50 acres of land could be fallowed in the equivalent of time so lost during a year. If the season turned out dry and late, as it did this year, these 50 acres would be of great advantage to the farmer. It was better to work 20 acres thoroughly, and perhaps obtain a 30bush. crop, than to work 40 acres in a slovenly manner and perhaps not get 15bush. to the acre. This was the fault of some of the farmers in this district. A great advantage of mixed farming was that money was coming in every week, and it was not necessary to wait for the one cheque each year. It was essential to look after the details. Mr. Wood wished to know if it were advisable to fallow land on the Island. Mr. Turner stated that for three years on one paddock he could not obtain a return of seed. He then fallowed the land and obtained an 80bush. crop of barley. Mr. P. T. Bell stated that he had fallowed and had obtained a worse crop than before. The ground was too wet. He would not recommend fallowing in the back country, as the rainfall was very heavy. Mediah was considered the best wheat for hay in this district.

Longwood, September 28.

(Average annual rainfall, 37in.)

PRESENT.—Messrs. W. H. Hughes (chair), H. Winter, J. C. Blakley, J. Nicholls, J. Roebuck, A. F. Furniss, G. W. Doley, J. R. Coles (Hon. Sec.), and two visitors.

HOMESTEAD MEETING.—This meeting was held at the homestead of the Chairman, Mr. W. H. Hughes.

TRIFOLIUM SUBTERRANEUM.—An inspection of the property revealed the fact that this clover took possession of the ground, killing other grasses. It was agreed that it was a good plant and would withstand a lot of feeding, but a decided drawback was that after killing the other grasses it was itself gone by autumn, leaving the ground bare.

IRISH BLIGHT AND BURGUNDY MIXTURE.—One of the members reported that he had dipped 18½cwts. of potatoes for seed in Burgundy mixture, made with 1½lbs. of soda, 1lb. of bluestone to 10galls. of water, just before planting at Christmas time. From an even crop there was not 6lbs. of affected tubers. There was every indication that the seed potatoes were affected by the blight, as 1½cwts. were so bad that they had to be picked out and destroyed.

Meningie, September 28.

(Average annual rainfall, 19in.)

PRESENT.—Messrs. A. Ayres (chair), Hill, Scott, Taylor, Yates, A. and E. Dainty, W. Tregilgas (Hon. Sec.)

PIG RAISING APART FROM DAIRYING.—Mr. W. Tregilgas dealt with this subject as follows :—A man could make a living in this district with about 100 acres of medium quality land worth from £2 10s. to £3 an acre. He should put in about 20 acres of lucerne, fenced off into four paddocks, for grazing purposes. Fifty acres under wheat should return about 600bush. of grain—sufficient to bring from 150 to 200 pigs to the most profitable weight for marketing. A pig of more than 120lbs. or 130lbs. weight required a good deal more feeding to produce a pound of pork than a lighter one. He would get 10 of the best sows procurable and one boar. At a low estimate these sows should give 150 young ones in the year. He found it more profitable to send dressed pork than live pigs to the market. With proper management they could be sent as pork during the hottest months, which was not practicable with live pigs. The wheat should be boiled before being fed, and 4bush. fed to a weaner of eight weeks old would last 10 weeks and bring it up to the 100lbs. weight. With lucerne grazing this amount of wheat would last much longer. As an estimate of the income that might be expected he quoted 150 pigs weighing 120lbs. each and valued at the reasonable rate of 4d. per pound, which worked out to £300. The owner would do most of the work himself, but would probably contract with someone to take his crop off instead of purchasing the expensive machinery necessary. It should not be difficult to get 600bush. from 50 acres of wheat, as the farmer would cultivate such a small area properly and get as much from it as a man with a larger holding and more slipshod methods would reap from 100 acres. The breed of pigs to keep was a matter of opinion, but he preferred the Berkshires. The sows of this breed had a tendency to eat their young, but that difficulty could be overcome by giving them some meat occasionally. Very little discussion followed. Mr. Yates considered the Essex the most profitable breed of pigs to keep.

Mount Pleasant, September 20.

(Average annual rainfall, 27in.)

PRESENT.—Messrs. H. A. Giles (chair), P. and J. S. Miller, T. C. Phillis, G. A. Vigar, D. C. Maxwell (Hon. Sec.).

RETENTION OF AFTERBIRTH.—Considerable discussion took place on this subject. One member suggested the insertion of about 3ft. of guttapercha tubing into the womb. The protruding end should have a funnel in it, and into this a mixture consisting of about a double-handful of common washing soda in a bucket of milk-warm water should be poured. The tubing should then be gently removed, and, as a rule, it would be found that the afterbirth would come away. If this should not be the case the treatment should be repeated, and in any case it would have a tendency to cleanse and heal the internal organs. [The opinion of the Veterinary Lecturer, Mr. F. E. Place, B.V.Sc., M.R.C.V.S., was sought respecting this treatment, and he replied as follows :—"The mechanical part of the proceedings as described is advisable, but will not always succeed. The amount of soda suggested is too high for general use, although it does no harm in this particular case. It would be preferable not to use more than 2ozs. or 3ozs. to the gallon."—Ed.]

Morphett Vale, October 15.

(Average annual rainfall, 22½in.)

PRESENT.—Messrs. H. V. Sprigg (chair), F. W. Crittenden, F. Rosenberg, J. Perry, T. and A. Anderson, T. Higgins, A. Connole, E. E. Hunt (Hon. Sec.).

ROTATION OF CROPS AND SHEEP.—Mr. H. V. Sprigg read a paper on this subject, which he also read at the Conference of Hills Branches of the Agricultural Bureau. This will be found printed on page 476 of the current issue.

Narrung, October 18.

PRESENT.—Messrs. Thacker, Hackett, Barker, Bowyer, E. Neville, Harwood, Clarke, S. Bottrill, Bolger, Critchley, S. E. Morgan (Hon. Sec.), and several visitors.

HOMESTEAD MEETING.—Members of the Branch assembled at the Narrung homestead, and took the opportunity of visiting the stock and crops. Much interest was taken in the pony stallion Roman Warrior and the Red Pole and Hereford cows. A nice plot of lucerne, which had been growing for about 12 years without cultivation or resowing, was inspected, and a small plot of strawberry clover, growing on heavy ground, was thought to be a useful fodder. This grass grew to a height of about 18in., was green all the year round, and stock were very partial to it.

DAIRYING INDUSTRY.—In the evening, the Government Dairy Expert, Mr. P. H. Suter, delivered a lecture at the Narrung Institute before a large audience.

Willunga, October 5.

(Average annual rainfall, 25½in.)

PRESENT.—Messrs. Pengilley (chair), Binney, Blacker, Waye, Hughes (Hon. Sec.).

CONGRESS.—After giving their report of the proceedings at the Annual Congress, the delegates expressed the view that too much time was wasted by representatives of Branches in discussing various matters. It was suggested that a time limit of five minutes should be fixed for delegates' criticisms. In some cases persons took up about a quarter of an hour in empty criticism, whilst other men, who had perhaps something of value to impart, were crowded out for want of time. Mr. Hughes suggested that a secretaries meeting could be arranged during the sittings of Congress, and expressed the view that a great deal of practical good should follow this step.

Woodside, October 23.]

(Average annual rainfall, 31in.)

PRESENT.—Messrs. R. P. Keddie (chair), W. King, W. Morcom, F. Baldock, G. Johnston, H. Rollbusch, G. J. Sampson, J. W. Disher, J. A. Morcom (Hon. Sec.).

WORKING SMALL HOLDINGS.—Mr. F. Baldock contributed a paper on the subject of the best means of making a small farm of 40 or 50 acres pay. The land should be cleared, he said, but enough timber for fuel and shade for stock should be left. It was advisable to divide the area into paddocks of five or six acres each, in order that the stock might be changed frequently. Good sheds should be built, and the stock housed at night and well bedded in the cold weather. Manure from the stables should be allowed to rot before being used. Eight or nine acres should be planted for hay and peas, and about two acres with different fodders, such as early green feed, mangels, maize, and chou moellier. It was not advisable to feed chou moellier to milking cows, as it tainted the milk and butter. One good horse would do all the work on the farm. A mare should be kept for breeding purposes, and she should bring in a profit of about £12 to £15 per year. It was not advisable to keep the progeny too long. Five good cows should be kept to come into milk at different periods, in order to yield a supply of milk and butter all the year round. They should be well fed, and the food should be changed as often as possible, with a regular time set for milking and feeding. They should bring in a profit of about £35 to £40 per year. Two pigs were sufficient, and the progeny from these should be marketed when four months old. The young pigs should be given a little pollard with milk for two or three weeks, and then fed on soaked peas. Pigs should bring in a profit of about £12 per year. About 30 fowls should be kept, and two or three hens set at the beginning of April and again in August, in order to obtain summer and winter layers. By selling eggs and young fowls a profit of about £16 10s. should be made. Half an acre of potatoes would return a profit of £8 or £9. Calf skins and other small items should yield about £3. Milk, eggs, bacon, poultry, fruit, and vegetables formed the most of the foods for home consumption. All waste vegetables should be boiled for pigs and fowls. If worked properly there was little expense on a small farm.

Uraidla and Summertown, October 7.

(Average annual rainfall, 42½in.)

PRESENT.—Messrs. E. Hart (chair), J. Rowe, H. F. Johnson, T. Day, Pappin, Kessell, Squires, T. Collins, R. N. Cobbledick, E. Hawke, G. Prentice (Hon. Sec.).

GENERAL FARM MANAGEMENT.—A paper on this subject was read by Mr. R. N. Cobbledick, the text of which will be found on page 489 of the current issue. In discussing the subject, members generally agreed with the ideas embodied in the paper. Mr. T. Day thought an effort should be made to regulate the crops, as by this means a good deal could be done in the way of obviating a glutted market. Mr. Rowe was of the opinion that members should generally utilise the railway facilities for marketing their produce more than they were in the habit of doing. In reply to various points, Mr. Cobbledick said that it was his view that the plough was better than spades for cultivating, as the work could be done more often and it was cheaper.

SOUTH-EAST DISTRICT.

Glencoe, October, 21.

PRESENT.—Messrs. H. A. Cameron, M. D. Cameron, A. Dow, J. Dow, J. Holloway, W. Lehmann, J. Riddoch, jun., F. A. Telfer, G. F. Ferguson (Hon. Sec.), and one visitor.

CURL LEAF FUNGUS.—The Hon. Secretary reported the prevalence of curl leaf fungus on peach trees after the foliage had appeared. He had sprayed with Bordeaux mixture when the buds were swelling, but owing to the rough nature of the weather the spray had been ineffective. Mr. J. T. Halliday (a visitor) had tried all kinds of spraying compounds, but his efforts had been unsuccessful. He believed in cutting the trees hard back at the end of the season occasionally, and also the practice of summer pruning as the best means of coping with the pest. Mr. M. D. Cameron had one tree which was so badly affected for three years that he anticipated the death of the tree, but it had seemed during the past two seasons to have thrown off the fungus and excellent crops of fruit had been secured.

Keith, September 29.

PRESENT.—Messrs. Morcom (chair), Williams, Tyner, Packer, Thompson, Schultz, Fulwood, Pearson, Aberle, Godlee, Hutchings, Leishman, Graves, Dall, and Lock (Hon. Sec.).

LAMBS FOR EXPORT.—Mr. Williams read a short paper on this subject, in which he stated that he preferred the Shropshire ram for breeding lambs for export in this district. He would procure a draft of ewes from 6-tooth to full mouth, and of as large and coarse a frame as possible. They should lamb about the end of June. He would sow rape and mustard on stubble ground in order to catch the first rains. It would then get a good start before the cold weather set in. Fifty acres of rape, provided it obtained a good start, should provide for 200 ewes with the lambs, in a 100-acre paddock. In about five months the lambs should be ready for export. In the discussion which followed, Mr. Packer thought it advisable to sow rape on fallow. The Hon. Secretary was of the opinion that a mixture of wheat, chaff, and bran was a good ration for ewes when feed was scarce. Bran was a good milk producer.

Lucindale, October 19.

(Average annual rainfall, 22½ in.)

PRESENT.—Messrs. Rayson (chair), Feuerheerdt, Langberg, Dow, J. McInnes, L. McInnes, F. D. G. Secker, Carmichael, Ferguson, Johnson, W. M. Secker (Hon. Sec.).

APHIS.—Mr. Feuerheerdt, in tracing the life history of the aphid, said that until this year growers in the south had been able to cope with this trouble, but they were now

experiencing some difficulty with it. When the peach trees were first blossoming, the first batch of aphids hatched out from the eggs. This batch consisted of both the male and female. The male was winged, and after copulation took place, died, and the female, being impregnated, produced impregnated females for the rest of the season, until a hot day was encountered, when she laid her eggs and died. These eggs were the starting of the brood for the following season's aphids. Ants have been observed carrying the aphids from one tree to another, and this had been explained on the grounds that the latter insect had on its back two projections out of which it exuded a fluid which the ants used as a food. Their object in transferring the aphids was to provide it with abundance of food in order that it might thrive and keep up a supply of the fluid. As a preventive measure he advocated spraying the trees early with either tobacco wash, kerosine emulsion, or resin wash. After the latter was used it was very difficult to clean the spraying outfit. Bisulphide of carbon had been used as a fumigant in the ground to prevent the eggs hatching, but as this would also kill the tree, its use was dangerous.

RED SPIDER.—Mr. Secker reported that last year he experienced a lot of trouble with red spider on part of a kitchen garden on which cauliflowers had been planted. This year beans were growing on the same patch, and they were likewise badly affected. Mr. Feuerherdt mentioned that the spider spun a web on the underside of the foliage on which it lodged, and this protected it from the effect of the spray.

Millicent, October 1.

(Average annual rainfall, 28½ in.)

PRESENT.—Messrs. G. Mutton (chair), H. Hart, J. J. Mullins, J. Bowering, G. G. Serle, W. Downs, H. Day (Hon. Sec.).

MAIZE.—A discussion took place with regard to the cultivation of maize. Mr. Hart expressed the view that this fodder would not grow well in the Millicent district on what could be termed the light swampy land, but on the heavy drained land it would be found to thrive well. Mr. Serle had secured some good crops of maize, but he had noticed that it was very liable to be affected by frosts. The Chairman had reaped a very profitable crop by simply broadcasting the seed on ploughed land and harrowing it several times. Horse Tooth was thought a suitable variety.

BUNCHY CROPS.—The Chairman remarked that he had noticed several crops in the district which grew very "bunchy." Mr. Serle expressed the view that the trouble was due to drilling in wet weather. The hoes became clogged, and on being cleaned an extra supply of super. was deposited. This did not prove, however, that the use of more super. would result in a heavier yield of grain, although the growth of the straw might possibly be heavier.

MANURE FOR POTATOES.—Mr. Hart recommended the use of lime as a manure for potatoes, especially in clean land. A first-class manure for this crop was secured by mixing 25lbs. of potash with 25lbs. of mineral super. Mr. Bowering mentioned that a mixture of wood ashes and stable manure gave excellent results.

Mount Gambier, October 12.

(Average annual rainfall, 31½ in.)

PRESENT.—Messrs. Wedd (chair), Watson, Wheeler, Major, Fowler, Sassanowsky, Bodey, Simes, G. Collins, D. Collins (Hon. Sec.).

ORCHARD PESTS.—Mr. R. Fowler, district inspector of fruit and vegetables, read the following paper:—"Naturally, the codlin moth (*Carporapsa pomonella*) will easily receive first place as the most serious pest to be found in our gardens, though it would not occupy that position in some orchards in the South-East. The codlin moth has now spread to almost every garden and orchard in the State, but that fact is no argument why measures should not be taken to keep it within reasonable bounds and reduce the loss caused by it. It is in neglected gardens that orchard pests increase and multiply; they practically become hatcheries, supplying fresh broods of pests and diseases to the careful gardener, and if any fresh serious pest comes along it is in these places it obtains a firm hold and breeds up. To successfully cope with the codlin moth it is not merely sufficient to get a spray pump and some spray mixture, and at any odd time spray the trees. Careful and systematic attention must be given to various operations right through the season, and with regard to spraying there are several points that require attention. It is necessary

(1) to use the right mixture and the right strength; (2) to spray at the right time; (3) to put the spray where it is wanted, and in addition prepare the trees for the spraying, and supplement the spraying by attention to the bandages and the cleaning away of rubbish. The tree should be properly pruned, and by that I mean it should be treated in such a way that it will not be necessary when spraying to use a long ladder. The tree should also be well opened so that the spray can be applied to the inside as well as the outside, and bear in mind, when spraying for codlin moth, that it is the fruit and not the leaves that need to be sprayed. In most of the gardens I have so far visited the trees are much too high and thick, particularly the pear trees, and these should be opened by having the centres taken out. I would not advise reheading altogether by cutting back all the main limbs in the case of pears, as I am afraid the subsequent growth would be so strong that before the trees commenced to bear again they would be as high as ever. It is necessary to use the right mixture at the right strength, and it is now universally acknowledged that the best preparation to use is arsenate of lead, numerous brands of which are on the markets, in either the paste or powder form, at the strength of, in the case of paste, 1lb. to 20galls., and of powder 1½lbs. to 50galls. When spraying for any pest or disease it is well to know something about its life history and habits, and also something of the nature of the spray that is being applied. No good results would be obtained by spraying an insect pest with a fungicide or a fungoid pest with an insecticide, and these mistakes are sometimes made. I have seen apricots sprayed for shothole with Kedzie's solution, the old spray for codlin, and apples sprayed for codlin with Bordeaux mixture, which should have been used for shothole, and the gardener wondered why his apricots were scorched and the codlin was as bad as ever, though he had sprayed three times. I know of no spray that is a cure-all. No up-to-date orchardist uses any spray as such, as different pests require a different action from the spray. Thus arsenate of lead kills by poisoning, and is only effective with such pests as eat it (*mandibulata* or gnawing insects). Tobacco wash, resin compound, scalede, and red oil kill by coming in contact with the tender bodies of the insects. They are contact sprays, and are effective against all scales and aphides. These insects get their nourishment by suction (*Haustellata*), and would not be affected by arsenate of lead. The contact spray kills by burning or suffocating. Burgundy or Bordeaux mixture, which is a fungicide, acts by checking the spread of fungus diseases by means of spores. Neither of these mixtures is effective against codlin moth, aphides, or scales. As the codlin moth, in its larva stage, exists by gnawing and eating, it will be seen that a spray that kills by poisoning will be most effective, as, though perhaps a contact spray would kill, it would never be possible to get the contact, as the larvæ do not long remain on the outside of the fruit. At the present time the larvæ or grubs of the codlin which left the apples late last season are to be found in the grub stage, still only a very few will have changed into the moth, and will be found under the rough bark in crevices and knot-holes, particularly in the latter, where the half-rotten dead wood still remains. These larvæ will, in the course of the next 10 days or so, perhaps in some cases a little longer, according to the temperature and other conditions of the hiding place, change into a small reddish-brown chrysalis, and when the apple and pear blossoms fall and the young fruit is noticeable the moths will burst the chrysalis case and find their way into the open, mostly doing so at night. They soon pair, and the female commences to lay her eggs, depositing them, in the case of the first brood, rather in or near the calyx of the fruit: so the first spraying should be done immediately the blossoms fall and while the calyx lobes of the fruit are still open. The spray should be put on in such a way that the hollow cavities of the young fruits are well filled with the arsenical poison. The young grub, when it hatches from the egg, which will be in a few days from the time the egg is laid, immediately begins to eat its way to the centre of the fruit to get at its natural food, the pips of the fruit. At the time it comes from the egg it is a very small thing indeed, and would hardly be visible to the naked eye but for its tiny black head. In about three weeks time the caterpillar is fully grown, and it then tunnels its way out of the fruit. If the fruit has not already fallen to the ground, which is very often the case, it spins a silken web and lowers itself either to a limb of the tree or to the ground, and it then crawls for refuge either to the tree stem or any other available shelter to spin a cocoon, change to a chrysalis, and again emerge as a moth. This cycle is repeated twice, if not three times, during the season. I have said that the first spraying should be done when the blossoms fall, but as the moths do not all come out at the same time, and the female does not lay all her eggs at once, and the fruit grows rapidly at this time, it will be seen that a second spraying will soon be necessary to cover the unprotected portions. This is usually given about a fortnight after the first, and is followed by a third three weeks or a month later, and with late varieties of apples a fourth should be given. It is the second generation of moths that gives rise to the most destructively numerous

brood of caterpillars, and the more effectively the first spraying is done the smaller in numbers will the second generation be. The second and subsequent broods are laid anywhere on the fruit, and the idea is to keep a constant film of the poison covering all parts of the fruit, so that whenever the young grub makes its attack it will get a dose of poison. Briefly summed up, to treat codlin moth effectively it is necessary to prune trees to within easy reaching distance from the ground, scrape off and burn all dead bark from the trunks and limbs, pay particular attention to knot-holes and crevices, and saw off any split or broken limbs on apple, pear, and quince trees; and do this at once, as in a week or two it may be too late to catch and kill any grubs hiding there. Spray with an approved brand of arsenate of lead when the blossoms fall, and repeat the spraying three or four times. Remove all vegetable growth, stakes, stones, old fences, &c., from round or near the trees. Place bandages on the trees before the end of November. Look through them every eight or nine days, killing any grubs found in them, and later on pick and destroy any infested fruit found on the trees or on the ground. All grubs with black or brown heads are not necessarily codlins. The grubs which caused so much damage in the early part of the season in the potatoes were the larvæ of the potato moth (*Lila solanella*) and not of the codlin moth, as is often asserted. It is often said, 'What is the use of my spraying or doing anything if my neighbor does nothing?' and that argument, while one simply puts on bandages and picked infested fruit, is unanswerable; but that is not the case now. In the bandages one only catches the grubs after they have destroyed the fruit, and no matter how many one catches the neighbor keeps up the supply, but by spraying the grubs are destroyed before they spoil the fruit. So no matter how ineffective one's neighbor's methods may be if the spraying is properly carried out one will reap the benefit. With regard to other insect pests there are only a few to which I need refer. The gardens I have visited have all been more or less affected with apple mussel scale (*Mytilaspis pomorum*), and, though rather late to deal with it, some steps may still be taken. This scale is described by French as a most destructive pest, and though at present not doing much harm, it is not wise to allow it to get too numerous. I would suggest that badly infested trees should be painted or sprayed on the lower limbs with either red oil emulsion, scalede, or kerosine emulsion. As all these mixtures will injure the foliage, care must be taken in using them. A vigorous brushing with a stiff brush will remove the dead scale from the limbs. Another insect pest noticeable in the gardens is the harlequin fruit bug (*Dindymus versicolor*). The eggs of this noxious insect are deposited during the late summer months amongst rubbish, under logs, stones, crevices of old posts, and in decayed wood. The young on being handled emit an abominable odour. They do a certain amount of harm to the fruit by inserting their nostrums, or beaks, into or through the skin, extracting the juices and causing the fruit to spot and become disfigured. The only remedies I can suggest are a free use of lime or sulphur, scalding with hot water, or spraying with tar water of the consistency of 1lb. to 50galls. Other insect pests which cause considerable trouble at times are the black aphid of the peach (*Myzus cerasi*) and woolly aphid, or American blight, of the apple (*Schizoneuria lanigera*). Time will not permit of my going into a description of these insects. I would suggest as treatment spraying with scalede or red oil in winter, and with tobacco wash in summer; and in the case of woolly blight the spray must be well driven in with considerable force, as the woolly down acts as a natural protection to the bodies of the insects. As they increase with alarming rapidity it is necessary that the spraying should be repeated every two or three days for a time. A good hot wind in November considerably checks these pests. The curculio beetle (*Otiorhynchus cribricollis*) has been found a hard pest to deal with. Placing traps filled with red oil has so far been found the most effective remedy. Tying woolly bands around the stems is another good plan. The chief fungoid diseases are peach curl leaf (*Exoascus deformans*) and shothole of the apricot and plum (*Phyllosticta circumscissata*) and black spot of the apple and pear (*Fusicladium dentriticum*). It is now too late to effectively deal with curl leaf fungus, but shothole can still be sprayed with some good results to the trees with a 1 in 10 solution of Bordeaux or Burgundy, and it is still time to treat apple trees for black spot. It must be remembered that the mixture is a preventive, and must be applied in time to anticipate the attacks of disease. The mixture is meant to destroy the spores of the fungi wherever it comes in contact with them. It therefore follows that the whole of the surface, under as well as over, should be coated with the mixture. It goes without argument that rainy or very windy weather is not suitable for spraying: a dull day is also preferable to a very hot one. The best time to apply the Bordeaux is just when the buds are bursting, or when the colors of the folded petals of the flowers are just visible. This black spot is a very serious disease in damp localities, and in such places it is not advisable to plant apples that are very subject to it, such as Cleopatras, for instance." In reply to questions Mr. Fowler said he had

not seen many curculio beetles at Mount Gambier, but had heard that they did considerable damage to roses here. Mr. Watson had seen the Bordeaux mixture very effective when properly used, and also the arsenate of lead for codlin moth, but both must be applied at the proper time. He suggested that it would be a boon to small orchardists if someone would arrange to spray their trees for them at a specific fee. The Chairman said it was a good thing to spray more than once for shothole in apricots, and the trees might be sprayed when the fruit was as large as marbles, or even bigger. Mr. Watson would like to see some scheme worked out to enable small orchardists to have their trees regularly sprayed. He spoke very highly of the benefit of spraying, which, he thought, saved up to 90 per cent. of the fruit.

Wirrega, August 24.

PRESENT.—Messrs. C. F. and E. Meier, F. L. and A. Densley, H. Laurenti, H. Exton, H. Rogers, W. Fairweather, W. Goldsworthy, S. Purdie, C. and R. Williams, L. Cook (Hon Sec.), and two visitors.

FARM HORSES FOR NEW COUNTRY.—A paper on this subject was read by Mr. Meier—"I prefer to have young horses," he said, "because an aged horse cannot stand the wear and tear of starting a new farm. I favor a good medium draught, short coupled in the back, with good sound legs, not too long and with flat bone. The high-priced and extra heavy draught can be procured later on. A man cannot feed his horses by weight, as some require much more feed than others. With a very little observation he can find out what his horse will eat, and then give him as much as he will clean up. If the feeder is cleaned right out, give him a little more next time. The feeder should always be empty in the morning, as the chaff if left in the feeder will soon become sour, and the horse will not take a proper meal from it. It is very important to have the stable well protected from draught, with plenty of ventilation at the top of the wall, high enough for the draught to pass over the animals. When warmly stabled—horses do not require nearly as much feed as they would if left in an open yard. Clean the stable out every morning. It will then be dry by night, and less bedding will be needed. To keep horses fit and well attend to the grooming. As soon as the sweat has dried a little in the evening give the horses a thorough currycombing to remove sweat and dirt, and in the morning give a good grooming, paying special attention to the shoulders. If the horse has any sores do not touch him with the currycomb, but use the brush freely to remove all dirt. Long hair on the shoulders should be clipped, or it will become matted under the collar and will chafe the skin. Clip the hair off as closely as possible around the sores, and above all things keep the collars clean and smooth. In the general handling of the horse be as gentle as you can, as the quietest of horses are easily excited, and a horse will remember an unjust blow longer than the man who gave it. A steady hand on the rein and a quiet word will do more good than a jerk on the mouth or a bang with a spreader. If you must use the whip, give one or two smart cuts, and afterwards treat the horse as if nothing had been wrong. Nothing is gained by bullying a horse for half a day for the least thing wrong. It will only make him pigheaded, besides knocking the others about. A mistake often made in this sort of country is over-loading the team. Nothing takes the heart out of a horse more than making him pull more than he can manage with comfort. It is better to make an extra trip than to spoil the team for the sake of gaining a day. After horses have had a spell it is advisable to work them lightly for a week to get used to it again, and also to set the shoulders."

Wirrega, October 5.

PRESENT.—Messrs. H. Exton, C. F. and E. Meier, R. Williams, W. Fairweather, A. and F. Densley, L. J. Cook (Hon. Sec.), and five visitors.

FARMING IN MALLEE COUNTRY.—Mr. Rae, a member of the Tatiara Branch, who had been working land of a similar class to that of the Wirrega district for some years, gave the following interesting notes. "I consider our first thought should be to prepare an area on which to grow hay, as in my opinion this is the most important item connected with farming. Every day taken to cart chaff is a day wasted. I would suggest that the best piece of land in the section be chosen. The denser the scrub the better. If gum country, cut the timber as close to the ground as possible, and make a thorough job of it. It will be repaid at harvest, when time is much more precious. It may save a broken knife-bar, a broken pole, or some other more or less costly break: also save a

trip to Bordertown and possibly a two days' wait for the new part. Then plough with as much draught as the team can manage in order to break as many roots and pull out as many stumps as possible. Do not use the cultivator in preference to the plough. Personally I do not favor the cultivator, and have yet to see the one that will work satisfactorily in this class of country. Sow slightly over a bushel of seed per acre, as the plant does not stool to any great extent here. Apply as much manure as possible, say 150lbs. per acre. My experience is the heavier the dressing of super. the heavier the crop. I have taken five crops of hay in succession from one paddock, and the quantity of super. and yield per acre have been as follows:—First year—75lbs. Law's super., yielded 9bush. oats per acre; second year—90lbs. Mt. Lyell super., yielded 12cwts. hay per acre; third year—120lbs. mineral super., yielded 15cwts. hay per acre; fourth year—150lbs. guano super., yielded over one ton hay per acre; fifth year—150lbs. guano super., yielded about one ton hay per acre. On new country the land should not be ploughed more than 3in. deep, as the subsoil is too sour for the first year. In preparing for the main crop all rolling should be done in March or April. There is then a good percentage of the sap up the tree, and when cut the roots are deprived of a good portion of their strength. Let it lie until the following year before burning. There will then be shoots about 3ft. high, which will add to the fire and act as a double check on the roots. If these suggestions are carried out, there will be little trouble with shoots after cultivation. If there is strength to put in 1,000 acres properly, do so, but if only strength to put in 250 acres, be satisfied with this area. I would suggest that not less than 90lbs. be sown here. The grain crop does not need so much super. as the hay crop: 90lbs. will give as much head as would be secured from 150lbs., but not so much straw. I would also like to see more fallowing. When 500 acres have been burnt, put in 250 acres and fallow the remainder for the next year. I feel confident it will pay to do this, for there is nothing like fallow to sweeten the land. Where sheep are kept sow about 2lbs. of rape and mustard or thousand-headed kale to the acre. The last-named has done splendidly with me. After seeding is done plant a few fruit trees. If fortunate enough to have a patch of limestone on the land, make a small kiln and burn it; then put a small quantity around each tree and the result will be surprising. Under this treatment last year some of my trees made up to 7ft. of new wood. Also prepare a plot for English grasses. I have tried a great many kinds; and my experience is that for a winter grass *Phalaris commutata* has done exceedingly well. Buy an ounce or two and sow it in a small plot. When big enough transplant it with about 1ft. between the plants. Cocksfoot is also a splendid grass and grows well here. *Paspalum dilatatum* is worthy of a trial and is a good summer and autumn grass. The best clovers I have grown are Italian and Subterranean. Both being annuals, they must be saved for seeding. Lucerne does very well, but needs a lot of water and manure to make it a success. Couch grass does fairly well and is good for binding the sand. With a few pounds each of the above grasses one will soon have a nice grass paddock to act as a chaff saver. I cannot recommend the following, as they have proved almost a failure here:—'Prairie, Sheep's Burnett, Fog, Rhodes', Cowgrass, and Alsike clover.' A very good discussion ensued, especially in regard to the quantity of super. to apply. Several voiced their failure to see the necessity for more super. being applied to hay crop than to wheat. A discussion took place on guano super., which was acknowledged by several to give better results than ordinary mineral. Mr. Fairweather attributed this, not to the 1 per cent. of nitrogen, but to the fact that the phosphate in the guano super. in conjunction with our soils became more readily available to plants than was the case with mineral supers.

AGRICULTURAL PUBLICATIONS.

The following publications have been issued by the Department, and are available for distribution at prices mentioned:—

Pruning of Fruit Trees, by G. Quinn, 1s. 3d.; posted, 1s. 7d.

Vinegrowers' Manual, by A. Sutherland, 6d.; posted, 7d.

Reports of Conferences of Australasian Fruitgrowers held at Brisbane and Wellington, 1s. each, or 1s. 1d. if posted.

Journal of Department of Agriculture of South Australia, 1s. per annum in advance: 3d. per single copy to residents of South Australia; 2s. 6d. per annum to other places.

Any of the following Bulletins and Leaflets may be obtained by sending a penny stamp for postage:—

Agriculture, Miscellaneous: Agricultural Bureau Congress Reports; Agricultural Experiments; Amount of Spirits to be Extracted from a Ton of Raisins; Depth of Sowing of some Agricultural Seeds; Hints to Intending Irrigationists; Housebuilding in New Districts; Lucerne Cultivation and Management; Lucerne Harvesting; Milling Characteristics of Australian Wheats; Milling Experiments; Milling Qualities of South Australian Wheats; Reclamation of Land; Roseworthy College Farm Flocks; Roseworthy College Harvest Reports; Roseworthy College Permanent Experimental Field; South Australian Wheat Yield, 1907-8; Stage to Cut Wheat; Hay; Trial of Stone-Gathering Machines; Salvation Jane or Paterson's Curse.

Horticulture: Apple Mussel Scale; Bordeaux Mixture; Cidermaking; Curculio Beetle; Codlin Moth; Currant Industry; Defects in Export Apples; Fertilisation of Orchard Lands; Fruit Drying; Fruit Flies; Fruit Preserving; Grape Vine Mildews; Gumming Disease of Peach and Almond Trees; Selection and Planting of Fruit Trees; Irish Potato Blight; Peach Leaf Curl Fungus; Plums and Prunes; Preserving, Canning, and Drying Fruits; Production of Early Tomatoes; Remedies for Diseases of Fruit Trees and Vines; Some Notes on Almonds.

Dairy: Milking of Cows; Spaying of Cows; Taints and Flavors of Dairy Produce.

Stock: Branding of Stock; Stomach and Bowel Diseases of the Horse.

[Every farmer and fruitgrower should join the Agricultural Bureau. Write to Department of Agriculture for particulars.]

T. PASCOE,

Minister of Agriculture.

POINTS FOR PRODUCERS.

South Australian Butter in England.

In his report to the Minister of Agriculture, dated London, October 11th, the Trade Commissioner states—"The dairy show, under the auspices of the British Dairy Farmers' Association, was opened on Tuesday, the 8th. I feel sure you will be gratified to learn that Messrs. Taylor Bros., of Gawler, succeeded in obtaining first prize for both their salted and unsalted butter; and also that another South Australian firm, Messrs. Lauterbach Bros., of Woodside, secured a 'Highly Commended' certificate."

Barley and Oats.

Commenting, in his estimate of the wheat harvest, on the probable yield of barley and oats the Government Statist (Mr. L. H. Sholl, C.M.G.), states:—"Last season 43,616 acres were sown for barley, and 224,781 acres for oats, and for this season the reports indicate an increased acreage for both cereals. In the South-Eastern Division the increase is general, and good yields of both grain and hay are expected. County Fergusson, with an increased acreage, reports barley crops 'fair to good,' and oats 'poor to fair,' and in the other parts of the State, where these two crops are grown to any extent, only a fairly good general yield is expected."

Bee Scouts.

Mr. F. A. Joyner writes—"A theory has frequently been put forward to the effect that the final location of a swarm of bees when it leaves a hive is determined by scouting members of the swarm. I have had very considerable doubt as to the correctness of that theory. My view has recent'y been to some extent modified by an experience which should interest your beekeeping readers. In each of the past three successive years a swarm of bees has taken possession of a cavity in the walls of my house at Bridgewater. The entrance to the cavity is through an open joint in the timbers, and is high up under an overhanging roof. The fact that three separate swarms should find their way to such a secluded and comparatively dark abiding-place affords to my mind some evidence of their being guided by scouts to a new home." Commenting on Mr. Joyner's letter, the Inspector of Apiaries (Mr. T. E. Whitelaw) states:—"The theory that swarms, when undisturbed by human

agency, finally locate in situations determined by scouts, is usually studied from two standpoints—(1) That scouts are sent forth previous to the swarm issuing from the hive. (2) That scouts are sent away after the swarm has issued from the hive and have clustered on some object near at hand. The whole matter is one that is difficult to obtain conclusive evidence upon. There have been many experiences somewhat similar to the one described that appear to be due to some system of scouting. It would be interesting to know whether the swarms in question went direct from the hive to the roof without clustering first.”

The Manufacture of Casein.

The dried curd of skim-milk, which is commonly called casein, is destined to become a big factor where creameries exist. Now that the direct cream supply is the principal system employed in this State only in a few cases could the manufacture of casein be employed, and it is doubtful if it would prove payable. Some little time back a company for casein manufacture was co-operating with a Victorian butter factory, but at the present time it is closed down. Casein is produced by curdling the milk with a weak solution of sulphuric acid and then expelling the moisture in the same manner as that employed in the early stages of cheese-making, namely, by heating and stirring. After the whey has been run off the curd is then pressed in the cheese press, and it is then passed through a special mill to tear the curd into small pieces, after which it is passed into a steam dryer, out of which it comes as hard as flint, and is ready for shipment. One hundred pounds of skim-milk will produce 3lbs. to 3½lbs. of dry casein. The residue, or rather the whey, from the casein is practically as good as the whey from cheese for feeding purposes. The purposes for which casein are required are numerous, amongst which are those used for paper sizing, wood filling, in the manufacture of paints, pencil erasers, adhesives, and substitutes for ivory.

The Importance of Lime.

The effect of lime on the soil (says the *Mark Lane Express*) is threefold—nourishing, chemical, and physical. (1) Its effect as plant food.—Lime is an absolute necessity for the growth of plants, although the requirements of the different crops vary in proportion. Leguminous plants of all kinds are especially exigent for a liberal supply. Soils unable to support a crop of clover may be brought into a condition to grow a plentiful one by a dressing of lime. Roots, cereals, garden produce all require a soil well stocked with lime; indeed, nearly all plants exhibit a strong, healthy growth in soils where lime is sufficiently present, assuming, of course, the other plant foods

are also in abundance. Under its influence the plants develop more powerful root growth, more solid structure, and greater capacity to withstand disease. Fodder crops produced in lime-rich soils contain better nourishing qualities than crops grown in lime-poor soils. (2) The chemical effect of lime.—The soil is sweetened by application of lime. The mineral food constituents in the soil, such as potash and phosphoric acid, are rendered more quickly available by its action, and it causes a more rapid decomposition of the organic substances by encouraging the activity of bacteria. Soils that, in consequence of sourness, are unable to grow satisfactory crops are soon changed by the action of lime into a healthy condition. (3) The physical effect of lime.—The physical and mechanical condition of soils is improved by applications of lime; it makes the soil looser, warmer, and more friable, more easily tilled, and not so liable to crust on the surface. Cold stiff clays are wonderfully improved by its action.

Natal Wattle Bark.

Natal wattle bark finds its way chiefly to Germany. The tanning trade in England favors tanning extracts. Last year the price of wattle bark on the London market ranged from: £7 18s. 9d. to £8 10s. per ton. Twenty years ago the price was as high as £16, while it has been as low as £7 5s. In 1911 South Africa exported bark to a value of £289,557, so it has become an industry of considerable importance to Natal, practically the only source of supply at present.—*South African Farmers' Advocate*.

Dependent Britain.

As a nation we pride ourselves on our independence (says the *Mark Lane Express*), but, as a matter of fact, we are, perhaps, the most dependent people on the face of the globe, inasmuch as we have to depend on our neighbors not only for our luxuries but actually for our daily bread. Now and then we are brought face to face with this fact. A little more than a year ago, when the railway service broke down temporarily on account of the strike, we realised how near we always are to starvation; and now, again, when, owing to foot-and-mouth disease, the removal of store cattle only across the Irish Sea is stopped, we have the grazier finding out how utterly dependent he is on his Irish neighbor, while the butcher finds himself in the same position, and with him eventually the consumer. Mr. C. Bathurst, M.P., has recently brought forward a scheme by which our country might lay in a store of grain for times of emergency and corn-growing could be made profitable to farmers. Whether it will ever take other shape and become more than a scheme remains to be seen; but, at any rate, it shows us where we stand, and how entirely dependent we are.

An Interesting Experiment.

An interesting experiment has been made this season at Gulval, situated right in the centre of the largest early potato district in West Cornwall, to test the value of an application of sulphate of ammonia to the crop. The land is described as having a southern aspect, and the character of the soil is loam. This season a trial was made to find the effect of a dressing of sulphate of ammonia against the dressing of another nitrogenous manure. The plots received the usual quantity of mixed dressing and guano, at the rate of 60 loads per acre, and 12cwts. of guano. Throughout the growth of the crop the plot that received the sulphate of ammonia showed superiority, which was confirmed when the crop was raised—the result being that from the sulphate of ammonia plot (one-tenth of an acre) 25 baskets of large and two and a half baskets of small potatoes were gathered; while from the other plot 19 baskets of large and two and a half baskets of small potatoes were taken. This experiment demonstrates that for early potatoes on such land sulphate of ammonia is an excellent fertiliser that can be depended on to produce very satisfactory results.—*American Fertiliser*.

World's Horse-Jumping Record.

The world's horse-jumping record, says the *Live Stock Journal*, was broken at Vittel, in the Department of the Vosges, at a horse show there. The Australian horse Beskra and the thoroughbred Montjore both cleared 2 metres 36 centimetres (approximately 7ft. 8in.), thereby beating the officially-recognised record hitherto held by the horse Conspirateur.

Application of Quicklime to the Soil.

The action of quicklime on the soil was the subject of a paper read by Dr. H. B. Hutchinson, Rothamstead Experimental Station, Herts, at the annual sessions of the British Association held recently at Dundee, Scotland. It was pointed out that the addition of small quantities of quicklime to field and garden soils stimulated general bacterial growth, but that large quantities caused an initial depression in the numbers of bacteria and a cessation of all biological processes. Dr. Hutchinson next read a paper on "Studies on Nitrogen Fixation." It is found that when plots of land were allowed to run wild for some years they showed a considerable accumulation of nitrogen in the upper layers of the soil. This has been attributed to the utilisation of the plant residues for nitrogen assimilation by free-living organisms. Dr. Hutchinson described the attempts which had been made at Rothamstead to induce similar changes in field soils. Barley plots which were taken for

experiments received spring or autumn applications of sugar or starch for some years. Spring applications of carbo-hydrates were made in the four years 1906 to 1909 and were followed by decreased crop yields. Autumn applications in 1909 and 1910 resulted in a decided increase of yield over the control plot.

Agricultural Value of Carbonate of Lime.

Professor James Hendrick, Marischal College, Aberdeen, contributed a paper on the agricultural value of carbonate of lime recovered as a by-product from causticising plant. In many parts of the country, he said, this precipitated carbonate of lime was thrown on the dump-heap as a waste product, while surrounding fields might be hungering for it. The soils of the north-east of Scotland were almost without exception poor in lime, yet this substance went to waste. A number of field experiments had been carried out with this carbonate of lime, in which it had been compared with other forms of lime, such as burnt lime and ground limestone. The experiments had all been made on land deficient in lime and very subject to finger-and-toe in turnips. So far as they had gone they showed that, whether the results were measured by increase of crop or by diminution of finger-and-toe disease, the precipitated carbonate of lime did at least as well as any other form of lime. It had, on the whole, acted better than an equal quantity of commercial ground limestone. This might be expected, as it was very much finer and was therefore more thoroughly mixed with the soil.

The Ills of City Life.

The following is taken from an address by Dr. L. Hill, M.B., F.R.S., before a meeting of the British Association :—" Conditions of city and factory life diminish the physical and nervous energy, and reduce many from the vigorous health and perfectness of bodily functions which a wild animal possesses to a more secure, but poorer and far less happy, form of existence. The illchosen diet, the monotony and sedentary nature of daily work, the windless uniformity of atmosphere, above all, the neglect of vigorous muscular exercise in the open air and exposure to the winds and light of heaven—all these, together with the difficulties in the way of living a normal sexual life, go to make the pale, undeveloped, neurotic, and joyless citizen. Nurture in unnatural surroundings, not nature's birthmark, moulds the criminal and the wastrel. The environment of childhood and youth is at fault rather than the stock ; the children who are taken away and trained to be sailors, those sent to agricultural pursuits in the colonies, those who become soldiers, may develop a physique and bodily health and vigor in striking contrast to their brothers who become clerks, shop assistants, and compositors."

Value of a Fertiliser.

When considering the value of a fertiliser, it should be borne in mind that the agricultural value—i.e., the effective fertilising capacity—and the “commercial value” of fertilising materials are not always in harmony. A fertiliser's agricultural value is determined by the increase produced by it in the crop. The commercial value of a fertiliser is dependent on the cost of the materials which enter into its composition. A fertiliser may have a high commercial value—i.e., it may have cost much to produce—and yet have a low agricultural value for a particular soil and crop. A fertiliser is dear to a farmer, even although it cost little, if its use does not result in a profit; a fertiliser is cheap, however much it cost, if its use increases the crop to such an extent as to leave a good profit.

Spanish Olives and Oil.

During the first three months of 1912 there were 58,230,616lbs. of olive oil distributed from Seville, Spain, a greater quantity than ever before during the first quarter of the year. Of this amount 1,156,113lbs. were shipped to the United States. During the same quarter 7,157,258lbs. of olives were exported to the United States.

Imports and Exports of Plants.

During the month of November 12,541bush. of fresh fruits, 3,246 bags of potatoes, 124 bags of onions, 3pkgs. of plants, and 142pkgs. of vegetables were examined and admitted at Adelaide and Port Adelaide under the Vine, Fruit, and Vegetable Protection Act of 1885; 542bush. of these bananas (chiefly over-ripe) were rejected. Under the Federal Commerce Act, 260 cases of fresh fruit, 2,620pkgs. of dried fruit, 41pkgs. of preserved fruit, and 3pkgs. of honey were exported to oversea markets during the same period. These were distributed as follows:—For London, 10pkgs. of dried fruits, 3pkgs. honey; for South Africa, 700pkgs. of dried fruit; for New Zealand, 1,885pkgs. dried fruit, 120pkgs. oranges, and 20pkgs. lemons; for India and the East, 120pkgs. apples, 41pkgs. preserved fruit, and 25pkgs. dried fruit. Under the Federal Quarantine Act, 8,411pkgs. of plants, seeds, bulbs, &c., were examined and introduced from oversea markets.

INQUIRY DEPARTMENT.

Any questions relating to methods of agriculture, horticulture, viticulture, dairying, &c., diseases of stock and poultry, insect and fungoid pests, the export of produce, and similar subjects, will be referred to the Government experts, and replies will be published in these pages for the benefit of producers generally. The name and address of the inquirer must accompany each question. Inquiries received from the question-boxes established by Branches of the Agricultural Bureau will be similarly dealt with. All correspondence should be addressed to "The Editor, *The Journal of Agriculture*, Adelaide."

GUMMING OF ALMOND TREES.

"W. G. R.," Adelaide, asks the cure for gumming of almond trees.

Reply—Mr. G. Quinn, Horticultural Instructor, writes:—"There is not to my knowledge any known cure for 'gumming' of the almond tree stem. The use of Stockholm tar has a tendency to keep caterpillars from boring the stem and aggravating the flow of gum, but it will not stop the exudation of gum, which is really degraded and congealed sap which bursts from the tissues. As far as investigations have gone the degradation is believed to be due to a fungus which finds an entry to the sap vessels *via* a wound. As far as I can observe here the Brandis, White Nonpareil, Peer ess, and other softshell almonds of local origin are more subject to 'gum' than the Californian varieties such as Hatch's Nonpareil, I.X.L., and Ne Plus Ultra. In consequence of this I advise using these sorts, and would suggest you seriously consider cutting yours off below the gumming area, paint the cut sections with Stockholm tar, and when young shoots are emitted and reach the diameter of a lead pencil or so, bud into a selected number one of the kinds named, preferably Hatch's. In a couple of years there should again be a good head upon the trees."

"S. H. R." asks—(1) If it is safe to apply liquid poultry manure to a 10-year-old lemon tree, and (2) the proper season for budding peach, apricot, and lemon trees.

Reply—Mr. Quinn writes—(1) In applying liquid manure, always water the trees freely, either immediately before or after the liquid manure is applied, as this dilutes it and minimises any injury which might possibly arise from the absorption of a strong dose. (2) *Budding*.—This operation may be performed at any time whilst the sap is active in the little stocks, providing, of course, buds for insertion are procurable. Usually the buds are taken

from the shoots of the current season's growth, and for peach and apricot you would probably have to wait till December here ; but lemon buds could be obtained at any time from spring time onwards. Buds inserted in lemon trees in the spring—say up till November—could be started into growth the same summer, but those put into stone fruit trees under the conditions indicated above are best left dormant until the next spring. They are kept dormant by not cutting the stock off above the inserted buds.

PLOUGHING IN STUBBLE.

"Scrub Farmer" writes:—"Would you recommend ploughing in the stubble and not burning off in light sandy soil, a good deal of which is over limestone?"

Reply—Neither on light sandy land nor on better soil is stubble burning, as a general practice, to be recommended. Further, light sandy soil will not stand frequent crops of wheat without an interval of rest, or, in the alternative, heavy manuring with a complete manure.

BLACK OLIVE SCALE ON ORANGE TREE.

"W. H. C." forwards an orange twig infested with black spots, and asks the cause and remedy.

Reply—The orange twig is infested with the insect called black olive scale (*Lecanium oleae*, Bern). It attacks nearly all kinds of trees and plants growing in gardens in this climate. Orange trees are most frequently affected whilst they are young and full of foliage, as the insect likes the shelter of dense growth. Such infested trees are also frequently covered with a black sooty incrustation, due to the presence of this scale. This sootiness is a mould fungus which grows upon the sweet, sticky exudations from the insects, and is not a parasite disease in itself; hence if the scale insect be destroyed, the sootiness disappears in time. This pest, though difficult to eradicate, is easily held in check. As a preventive measure, the infested trees should be thinned out where the twigs are dense and crowded, so as to admit light and sun heat, and by occasionally applying a spraying with resin wash, or oil emulsion, the insects are reduced to harmlessness. These emulsions may be made from kerosine and soap, or some of the heavy red oils, which may be bought in a prepared form readily mixable with water.

DRAKE.

"W. H. G. Z.," Buccleuch, asks—(1) What is drake? (2) To what extent is its presence in a wheat crop harmful? (3) What precautions should be taken to prevent its appearance in a crop? (4) What should be done to exterminate it?

Reply—(1) "Drake" is a weed, namely, *Lolium temulentum*. (2) Its presence in a crop is harmful in that it takes the place and nutriment which

otherwise might be used by a crop, the same as is the case with any other weed. (3) The best precautions to prevent its appearance in the crop is to carefully grade the seed wheat. (4) The weed is best dealt with by thoroughly cultivating the fallow to kill the plants.

STOCK INQUIRIES.

(Replies supplied by Mr. F. E. PLACE, M.R.C.V.S., B.V.Sc., Veterinary Lecturer).

Dry, Brown Patches on Sheep.

A member of the Koppio Branch asks the cause of dry, brown patches which occur on the necks and backs of sheep. The wool on these patches is shrivelled and short. Sheep on scrub and heath country are most affected.

Reply—It would be well to send a patch or two to the Chief Inspector of Stock, as probably the sheep are ticky or lousy, although the patches may arise from other causes ; but whatever the cause, the remedy would probably be found in dipping with a reliable arsenic dip.

TAINTS IN MILK AND ITS PRODUCT.

By H. J. APPS, Dairy Officer.

(Continued from page 110, September issue).

The cleaner the strainer the freer the milk is from contamination. Certainly one of the most common sources of infection is the habit of wet milking. Less could be said about this practice were the udder and teats of the cow thoroughly cleaned; but such is rarely the case.

If the first few streams of milk from each teat were milked into a separate bucket it would vastly improve the keeping quality of the remainder, and in some instances lessen the possibility of introducing organisms that may lead to taints. The bitter taste often associated with milk may be attributable either to the food, organisms, or the cows having been in an advanced stage of lactation.

As previously stated, the contamination of milk occurs frequently, as it always contains a varying amount of germ life. The result of this infection is to cause milk or cream to become fermented, yet it is possible that milk may acquire an abnormal taint, such as is due to absorption, without undergoing any fermentative change; but the invasion of various forms of bacteria is so common that fermentative changes, due to living organisms, are constantly at work.

Milk may become tainted from ---(1) Absorbing bad odors. (2) The dust and dirt that may get into the milk during and after milking. (3) Rusty and unclean utensils. (4) Cows eating unsuitable feed. (5) Cows drinking impure water.

We are all familiar with the ordinary souring of milk, which is pronounced if the milk be allowed to remain for a few days under ordinary temperatures. This souring of milk is due to the formation of lactic acid, which is produced by the decomposition of the milk sugar. This class of bacteria develop in milk with great rapidity. In this fermentation the acidity or sourness begins to be evident to the taste when it reaches .25 per cent. lactic acid. Cream never develops as much acid as milk, because there is less milk sugar in the cream.

PASTEURISATION.

With badly tainted milk pasteurisation may be used to advantage. The pasteurisation of milk when properly carried out will keep the milk in sound

condition for, on an average, 24 hours longer than would otherwise be the case.

The system cannot be successfully employed in creams which have become decidedly off in flavor and high in acidity. With cream which is thin or low in butter-fat the pasteurising has a tendency to cause the casein to become coagulated, which materially increases the loss of butter-fat in the butter-milk; therefore, to minimise this trouble to a degree, it is expedient that the cream be heated to 180° F. rapidly.

It is not an agent to totally kill the putrefactive germs, but is only instrumental in checking their growth in the early stages. Its general adoption is hardly practicable in most of our factories, as the cream delivered in the warm months is of a varying condition. It can only be successfully carried out where freshly separated creams are received; thus I am of the opinion that a more rapid cooling of the cream is of more vital importance, especially in the case of creams high in acidity and temperature.

Pasteurisation involves more labor and expense. The general type of the pasteuriser is a large drum surrounded by a steam jacket, and containing a rotary fan or stirrer, which is driven by a belt. This is necessary in order to agitate the milk or cream and prevent it from becoming burnt. The milk or cream is admitted at the bottom of the machine, and when stirred by the fan is passed through the outlet at the top, in which is inserted a thermometer, thus enabling a constant eye to be kept on the temperature. The process requires a considerable amount of steam and cold water. Pasteurising cream eliminates in certain cases bad taints and enables the butter-maker to secure a sound material for inoculation with a starter or lactic ferment, with the result that he has the complete ripening process under his care. The general temperature employed is from 157° to 180° F.

The sudden souring of milk after pasteurisation is, in many cases, due to the imperfect cooling after the milk has been heated. It becomes necessary in using pasteurised cream to employ starters, or lactic acid ferments.

The greatest care must be taken to sterilise all utensils used for the propagation of a starter. The starter should not be allowed to become too cold, because putrefactive ferments are apt to gain the ascendancy. A good starter has a clean, pleasant, acid taste. It is most effective if used very soon after coagulation or thickening, or with an acidity of from .65 per cent. to .85 per cent. lactic acid.

TO PREPARE A STARTER.

Take 4galls. of freshly separated milk sound in flavor and hold at a temperature of 180° F. for two hours, then rapidly cool to 90° and add your culture, either in the shape of liquid or powder form, and hold at a temperature of 88° F. This is allowed to stand until thickened in a sealed jar or vessel well covered with a cloth, which generally occupies from 18 to 24 hours, when it is ready to inoculate the pasteurised cream or milk. Sufficient

quantity of this starter, viz., about $\frac{1}{2}$ per cent., is used to propagate another 4galls. of pasteurised or sterilised milk, and such a procedure is carried on from day to day, until the starter shows signs of deterioration. Under ordinary conditions a starter should be sound for a period of from three to four weeks, at the end of which time a fresh starter should be made. The quantity of starter necessary for cream will vary from 5 per cent. to 12 per cent., depending upon the ripening or maturing temperature and the thickness, as regards butter-fat, of the cream.

THE ACIDIMETER.

By the use of the acidimeter one is enabled to regulate the ripening process, or the addition of a starter, in an intelligent manner. For the purpose of

A Cheap and Sanitary Milk House.

making the test a standard alkaline is used and kept in a well-stoppered bottle. A burette capable of holding 30c.c., a white dish, a 10c.c. pipette, a bottle of phenolphthalein indicator, and a glass stirring rod complete the outfit. The 10c.c. of milk or cream to be tested is measured into the white basin and two or three drops of the indicator is added.

The sodium hydrate or alkaline solution is now allowed to slowly drop into the basin containing the milk or cream, which is constantly stirred with the glass rod during the operation. The indicator give no color reaction in an acid medium, but as soon as sufficient of the alkaline solution has been

added to neutralise the acid, a pink tinge appears. The dropping of the solution is stopped immediately the pink color becomes permanent.

The number of c.c. of the solution, which is noted on the graduated burette, required to produce a pink color indicates the percentage of lactic acid present.

Have the solution of such a strength that 1 cubic centimetre will neutralise .01 grammes of lactic acid.

SEPARATING.

In some instances the butter possesses an over-ripe or sour flavor, besides being weak in body and greasy in texture; this is due to the high temperature at which the cream has been churned. Again, the most vital point is confronted, namely, that of expelling the moisture from the granules of butter. It is always noticeable that butter churned at a high temperature is found to be saturated with free moisture, and another serious difficulty met with is the comparatively large loss of butter-fat, which is daily taking place where proper cooling facilities are not available.

As the warm weather is approaching farmers should alter the cream screw of the separator and aim at delivering cream testing from 40 per cent. to 45 per cent. of butter-fat. It is no uncommon occurrence to find creams delivered with tests varying from 25 per cent. to 60 per cent. If cream is leaving the separator low in butter-fat it is either due to the cream screw not being properly adjusted, not sufficient speed, milk not being at the right temperature, inflow greater than the capacity of the machine, or through allowing too much milk to pass through the machine as the speed is decreasing, in order to flush it out. It is imperative for best results that freshly separated cream should not be mixed with a previous separation until at least from six to eight hours. Warm cream mixed with old cream will spoil the whole product, and even should the cream be cooled sufficiently the previous separated cream will cause the fresh lot to increase in acidity.

It has been proved beyond doubt that nearly all the chemical and bacteriological changes in cream take place in the milky parts, therefore the richer the cream the better it will keep, other conditions being the same. By separating a fairly rich cream there is less expense in cost of transportation, as cream is more valuable than milk. The three cardinal points to observe are—clean cream, cool cream, and fairly rich cream, which tell the secret of producing a good cream.

One of the conspicuous features of the present system of transportation on the railway, by coach, and ordinary farm conveyances is the prevalence of allowing the cans to become exposed to the rays of the sun. When such conditions exist it tends to produce a butter possessing a tallowy flavor.

GROCCERS' AND ALLIED TRADES' EXHIBITION, LONDON.

The following report on the South Australian exhibit at the Grocers' and Allied Trades' Exhibition, held in London in September, has been received from the Trade Commissioner :—

The London Grocers' Exhibition was opened at the Agricultural Hall, Islington, on Saturday, September 21st. The South Australian exhibit occupied a space of 60ft. x 16ft. in a prominent position in the hall. As usual, owing to the fact that this is essentially a trade exhibition, the attendance of the general public was not large ; but, what is more important to South Australian producers, the "trade" attended in large numbers, especially on the Wednesday and Thursday (early closing days), when at times it was difficult to walk about, owing to the crowds. Excursion trains were run from almost every part of the United Kingdom.

Posters were in evidence at all the principal railway stations, upon which the State of South Australia was brought well to the fore. In addition to occupying a prominent position in the ordinary posters, the notice in regard to South Australian produce was most prominent on the monster placards that were pasted up outside the hall.

Not only the South Australian exhibits but our methods of promoting the sale of the various lines shown were most eulogistically spoken of on all sides by visitors and the press. In almost every instance I was in a position to inform the "trade" where the various products were to be purchased in London, wholesale, and the public where they were to be obtained retail.

Wine.—The prominence we give to the various brands of South Australian wines that are on the English market is a source of gratification to the proprietors, who are fully alive to the importance of trade exhibitions as a medium for further introducing their wines to the "trade" and the public.

Apples.—In addition to showing the usual plate of exhibits of apples we also had the original package on view. While speaking of original packages I should like to take this opportunity of again sounding a warning note in regard to deviating from the present package, as I understand has been suggested. I intend, however, to deal with this question very fully in a separate report. South Australian apples being out of season, I was unable to specify any particular store where they were obtainable at the present, but on the cards over the exhibits the public were notified that South Australian apples were procurable at all leading fruit stores during the season (April to June).

Lambs' Tongues.—Learning that a Bristol firm still held some 60 cases of lambs' tongues that were packed at the Government Works, Port Adelaide,

I put a London wholesale house in touch with them, with the result that a deal was made and I was in a position to notify the "trade" that the tongues on show were also procurable in London. This wider distribution should assist me in getting a better offer when next the department has a further lot available for shipment.

Honey.—Owing to the method we have adopted of exhibiting honey, viz., arranging the jars on a skeleton stand with electric lights inside, it always proves a most attractive feature of the show. Unfortunately, I was not in a position to offer to the trade generally; but, as several of the large retail establishments in London still hold a small stock, I was in a position to refer the public to them. It is not my intention at any time to withdraw this line from the shows; because, although the supply at the moment is nil, I am convinced that sooner or later this market will again be required to relieve the local market, and accordingly I am of opinion that it would be a great mistake to withdraw it.

Eucalyptus Oil.—The trophy supplied by Messrs. F. H. Faulding & Company was an innovation to the stand, and from the results obtained I am convinced the firm will not regret their enterprise in taking advantage of the opportunity offered to them. Due to the fact that this particular brand was to be exhibited on the Government stand at the Grocers' Exhibition, Messrs. Faulding's representative in London was able to induce four of the largest retail emporiums in London to carry stock.

Dried and Bottled Fruits.—The dried and bottled fruits, together with the apples, occupied the centre of the stand, and was admitted to be the most attractive exhibit in the whole of this important exhibition. In connection with the exhibit I took the opportunity of again giving to the trade and the public full instructions in regard to the correct method of preserving dried apricots for desert purposes, also for jam making. With a view of carrying out my propaganda, some weeks before the exhibition was to be opened I approached some of the representatives of Adelaide firms in London whom I knew usually sold the fruit in London on account of the growers. I explained the methods I intended introducing, and suggested if I were enabled to carry them out it would be a good thing for the industry in South Australia. I also pointed out that without some stock to work on it would be useless to attempt my scheme. I regret to say that I failed to get any encouragement from these sources. Accordingly, sooner than let such an excellent opportunity go by of proving to the trade the superior quality of South Australian sun-dried apricots over those of other countries, I approached Messrs. Joseph Travers, Limited, the well-known wholesale merchants in London, who I knew held stocks of South Australian fruit. I explained my idea to them, when they at once fell in with my views and offered me every possible assistance. Messrs. Travers supplied me with a considerable list of retail establishments to whom they had sold South Australian fruit,

and who, in consideration of the fact that their names would be mentioned on a list given away at the exhibition, undertook to give South Australian dried apricots full prominence in their shops. Having the above in view, I had a quantity of circulars printed and distributed them from the stand in the exhibition, mentioning where the goods could be obtained. In order to further convince the public that jam of excellent color and flavor could be made from the dried fruit at a small cost, I had some jam made from the dried fruit and placed it alongside the general exhibit.

ADVISORY BOARD OF AGRICULTURE.

The monthly meeting of the Advisory Board of Agriculture was held at Roseworthy College on Wednesday, November 13th, on the occasion of the annual visit of the Board. There were present the Chairman, Mr. A. M. Dawkins, Mr. G. R. Laffer, Professors W. Lowrie and A. J. Perkins, Messrs. F. Coleman, G. F. Cleland, C. J. Valentine, C. E. Birks, and G. G. Nicholls (Secretary).

After inspecting the crops, experimental plots, &c., the necessary business of the Board was dealt with as follows :—

TWO NEW BRANCHES.

The formation of Branches of the Bureau was approved at Goode with the following gentlemen as members :—Messrs. E. A. C. Lutz, C. P. L. and K. H. L. Will, Wm. Burner, W. Folland, A. B. Geue, S. O. McPherson, J. G. Rohrlach, V. J. Tonkin, L. B. Hughes, W. G. Morcombe, S. W. Broadfoot ; and at Julia, with the following members :—T. Prior, D. S. Heaslip, A. and O. B. Pfitzner, J. G. Reuther, W. and P. H. Copley, J. Jaffer, W. Paterson, H. B. Martin, H. B. Traeger, J. McRitchie, R. A. and W. H. Neal, W. Hall, T. Brown, T. Neylon, T. Carter, D. Hombsch, and G. Gaerth.

NEW MEMBERS.

The following gentlemen were appointed as members of the undermentioned Branches, viz. :—Monarto South—R. B. Thiele ; Elbow Hill—A. McCallum ;

Petina--W. S. O'Grady ; Renmark--E. Williams, B. H. B. Williams, W. E. Snow ; Meadows--J. H. Williams, W. Milligan, F. Vickery, E. Vickery, T. Usher ; Millicent--G. Major ; Redhill--D. Robertson, T. H. Treloar, F. Jackson, C. Campbell, W. J. Button, W. Hayes ; Longwood--C. J. Phillips ; Forster--W. G. Retallack, J. Simms, J. Stone, W. C. Retallack, A. Schmall, G. White ; Moonta--A. B. Fergusson, P. Ford, J. Beaglehole ; Coorabie--O. Grimes, S. Shields, D. G. Roberts, A. Winter, V. R. Hardy, E. J. Stretton ; Amyton--A. J. Phillis ; Moonta--L. Howlett, Jas. Bowden, A. Bowey, P. Bowey, F. Symons ; Balaklava--P. H. Shepherd ; Clanfield--R. Correll ; Orroroo--E. Turley, J. M. Cadzow, L. Judell, W. H. Roberts, J. R. Chapman, H. Chapman ; Renmark--J. N. McDougall, H. S. Pike ; Hooper--G. Masson ; Crystal Brook--W. W. Forgan, J. H. Dingle ; Mount Remarkable--C. Yates, G. Yates, jun., E. Mayne, R. G. Fiebig ; Glencoe--J. T. Halliday, H. Halliday, A. Haines ; Monarto South--J. Hutton ; Wirrabara--H. P. Greenshields ; Riverton--T. Penny, T. Camac, T. Hall ; Mount Bryan--A. Woodgate, B. H. Woodgate, A. A. Jeffries ; Yadarie--A. Preiss ; Yallunda--G. A. Teakle ; Clarendon--J. Potter, J. R. Nicolle, H. G. Rowley, W. B. Burpee ; Meningie--A. G. Williams, F. W. Newson ; Northfield--E. Kester ; Hawker--A. E. Hirsch, P. P. Feineler.

LIFE MEMBERS.

The undermentioned gentlemen were appointed life members in recognition of 20 years or more consistent and useful membership in the Agricultural Bureau:—Lucindale Branch—Messrs. E. F. Feuerheerd and H. Langberg ; Carrieton—Mr. W. J. Gleeson ; Colton—Messrs. P. P. Kenny, R. Hull, and M. S. W. Kenny ; Narridy—Mr. H. Nicholls.

Charlton Apiary, Eyre Peninsula.

THE PRACTICAL VALUE OF A SOIL ANALYSIS.

(From *The Journal of the British Board of Agriculture.*)

Inquiries are frequently received by the Board from farmers and gardeners who wish to be informed where they can have soils analysed. In most cases the idea appears to be entertained that having a soil analysed is a ready means of determining its manurial requirements, or of obtaining an indication of its fertility. A brief discussion as to how far this view is correct may therefore not be out of place. Take, first, the broad question—to what extent does an analysis of a soil give an indication of that soil's fertility?

The fertility of a soil may be defined as its power of growing crops, and it is obvious that while this depends to a great extent on the soil's ability to supply the crop with what is often termed plant food—in particular, nitrogen, phosphate, and potash—in a suitable form, this is by no means the only essential condition. A sufficient and continuous supply of water to the roots, and proper aeration of the soil, are quite as necessary for satisfactory growth as the supply of manurial ingredients. To a very great extent these factors are regulated by circumstances of climate, exposure, drainage, and depth of soil, which obviously cannot be determined in the laboratory. Even if the analyst could give complete information about the plant food, and were able to measure accurately the mechanical condition (*i.e.*, texture) of the soil, and to correlate it exactly with the questions of aeration, drainage, and water supply, the information obtained in the laboratory could only give a very incomplete idea as to the fertility of any particular field, and the farmer would have to supplement it by his local knowledge, experience, and judgment.

Unfortunately, however, the analyst cannot at present give more than very rough and incomplete information even about those factors influencing fertility which lie within his province. Some of the difficulties with which he has to contend may be mentioned here. He can determine as accurately as need be the total amounts of nitrogen, phosphates, and potash in the soil, but it has been found that, even where external factors such as climate, depth of soil, &c., do not enter into the case, there is often little or no connection between these amounts and the soil's fertility or its manurial requirements. Any ordinary soil contains much more total plant food of all forms than a single crop of any kind can possibly require. Most of this plant food, however, is in an unavailable or locked-up condition, and is only gradually set free or made available, the rate varying in different cases. As the plant

can only make use of the free or available food, it is very easy to see that it is quite possible for one soil, containing quite small amounts of the manurial substances, to produce better crops than another soil containing large quantities, if for any reason the first soil gives up its material to the plant at a more rapid rate than the second. In fact, many soils contain very large quantities of, say, phosphates, and still respond most readily to small dressings of manures containing available phosphate, because practically all that is already in the soil is unavailable, and, as far as the plant is concerned, might almost as well not be there at all. (It may be remarked that exposure to air and weather, and treatment which secures a healthy condition of soil, are some of the factors which determine the rate at which plant food becomes available in the soil, so that, apart from their other important functions, good cultivation, draining, and liming may partly take the place of manuring in a soil which contains large stores of locked-up food.)

In the case of phosphates and potash, a method has been devised of roughly measuring the amount which may be regarded as of immediate or prospective value to the plant, by finding, not the total amount of phosphate or potash present, but the amount which is dissolved out in a given time by a weak solution of citric acid. This method gives results which in many cases indicate fairly well whether a particular soil will respond to applications of either of the two kinds of manure, and may be used in comparing soils of the same class. At the same time there are many cases where the results obtained are at variance with those obtained by actual experiment in the field. So far, no ready method has been discovered by which the availability of the nitrogen in the soil can be estimated except as regards the small amount present in the form of nitrates or of ammonium salts.

As already mentioned, two conditions essential for the satisfactory growth of crops are a sufficient supply of water and the proper aeration of the soil. To a great extent the ability of the soil to meet the plant's requirements in these respects is determined by the size and nature of the particles of which the soil is composed. By carrying out a "mechanical analysis," the proportions of particles of different degrees of coarseness can be measured, and as the results of such analyses accumulate, it will probably become possible to estimate from such an analysis such factors as water-retaining power, ease of drainage, ability to withstand prolonged drought, and so forth, and even to say with some degree of certainty what systems of cultivation are most likely to result in a good tilth at any particular time of year. At present, however, such an analysis is tedious and expensive, and in most cases an experienced farmer would be able to gain more useful and accurate information by walking over the land and examining it carefully at different times of the year.

On the whole, in the present state of our knowledge, it must be concluded (1) that chemical and mechanical analyses of soils are of little practical value except in a few special cases ; (2) that an intelligent and experienced local farmer could give a much better idea of the fertility of any particular farm or field than an analyst ; and (3) that as a means of determining the manurial requirements of a soil a simple field experiment gives more accurate and reliable knowledge than ordinary analyses.

In certain special cases, however, soil analyses may undoubtedly be of great practical value, *e.g.*, (1) by a very simple test, which most farmers could carry out for themselves, it is possible to say whether a soil is in need of liming or not ; (2) if, by means of a soil survey, such as those now being carried out in many parts of the country, complete information has been obtained with regard to some special class of soil occurring in a limited area, different samples of that particular soil can be compared and classified fairly accurately, and their manurial and cultural requirements predicted with a considerable degree of certainty.

THE WHEAT CROP.

Official Forecast: Probable Average, 9'03 Bushels.

The official estimate of the wheat and hay harvest for the season 1912-13 was issued by the Government Statist (Mr. L. H. Sholl, C.M.G.) on Wednesday, November 27th. The actual figures for the past season and the estimated ones for the present season are given in detail in the following pages. In the table below the official totals for the State are shown, together with the estimates of *The Advertiser* and *The Register*.

	Government Statist, Nov. 28th, 1912.	<i>The Advertiser</i> , Nov. 14th, 1912.	<i>The Register</i> , Nov. 19th, 1912.
	Acres.	Acres.	Acres.
Area under crop	2,658,715	2,601,853	2,701,131
Area to be reaped for wheat	2,229,890	2,181,853	2,225,253
Area to be cut for hay	428,825	420,000	475,878
	Bushels.	Bushels.	Bushels.
Aggregate wheat yield	20,137,870	19,409,592	19,893,761
Average per acre	9'03	8'53	8'94
	Tons.	Tons.	Tons.
Aggregate hay yield	457,290	—	465,646
Average per acre	1'07	—	19'57cwt.

The general character and lateness of the season made the work of the chief clerk (Mr. W. L. Johnston) and other officials of the Statistical Department more than usually difficult. The climatic conditions for the early months of the season, March to May, states the Government Statist, could not have been worse. Good general rain fell in June, and favorable conditions continued for July and the greater part of August. September and October were distinctly unfavorable. The rainfall was patchy and in most centres below the average, but the late sown crops were wonderfully revived by the exceptionally fine general rains which fell in November. The report shows that the total acreage under crop is 66,285 acres more than last season, and that the estimated production of grain is less by 214,850 bushels; and of hay less by 18,492 tons than in 1911-12. A decrease in the average yield of grain is anticipated for all the divisions of the State with the exception of the South-Eastern, the estimated average being 9'03 bushels as against 9'29 last year.

The following table shows the estimated averages per acre for each division in comparison with the actual for the previous season:—

Division.	Averages per Acre.	
	Grain. Bushels.	Hay. Tons.
Central	9'40 (10'12)	1'16 (1'31)
Lower North	11'83 (12'47)	1'16 (1'29)
Upper North	6'48 (7'09)	0'87 (0'94)
South-Eastern	8'47 (5'10)	0'93 (0'77)
Western	6'80 (7'87)	0'70 (0'87)
The State	9'03 (9'29)	1'07 (1'18)

L. H. SKOLL, Government Statist.

Statistical Office, November 27th, 1912.

AUSTRALASIAN FRUIT-GROWERS' ANNUAL CONFERENCE.

Report by MR. G. QUINN, Horticultural Instructor.

The Horticultural Instructor (Mr. G. Quinn) has forwarded to the Director of Agriculture the following report on the proceedings at the Annual Conference of Australasian Fruitgrowers, held at Sydney, New South Wales, on October 21st-25th, 1912 :—

“Delegates to the Conference were sent by fruitgrowers' associations in all of the States of the Commonwealth, and a representative from those of New Zealand was also present. Four of the State Agricultural Departments, viz., those of Tasmania, Victoria, New South Wales, and South Australia sent an official belonging to their respective horticultural sections. The agenda paper was a long one, no less than 30 motions, or amendments to motions being discussed and voted upon. Although the official visitors were given no actual status in the deliberations, we were able, in many respects, to correct misconceptions respecting the official attitude adopted toward questions of interest to fruitgrowers in the various States. Outside of assisting in this manner, when requested by the gathering, it was our object to try and feel the pulse, as it were, of the Conference, and to arrive at conclusions regarding the aspirations and various objectives which appeared to reveal themselves through the discussions.

SEA CARRIAGE OF FRUIT.

“Among the multitude of motions one fact seems to stand out most prominently, and this related to the defective carriage or transport of fruit, chiefly by sea. These discussions laid stress upon facts which have been pretty well known for some time in official circles in the different States. The motions submitted showed very clearly that this drawback existed equally in the Australasian coastal, as well as the European oversea services.

“In respect to the transport of fruit around the coasts a splendid demonstration has been given by the A.U.S.N. Co. in the carrying of bananas from Fiji to Sydney and Melbourne. This company has fitted up the s.s. *Levuka* with appropriate bulkheads, brine coils, and electrically-driven fans to ensure a cooled-air circulation, and bananas are carried in an absolutely perfect condition from Fiji to Melbourne, whence they are driving the Queensland grown banana out of the southern markets. Through the courtesy of the officer in charge I inspected this boat, when 33,000 bunches (equalling about 11,000 crates) had just been landed in Melbourne from Fiji with less waste than when

the average coastal steamer lands 200 cases of Queensland bananas in Adelaide. There is no question whatever, that unless the coasting steamship companies adopt a similarly effective method of carrying the fruit the banana-growing industry of Queensland must collapse, owing to the heavy losses incurred. It is to be hoped that their monetary interest in this trade will cause these companies to grapple with the difficulty before the business has entirely gone into the hands of the people who supply a better article from outside sources. These are results which stand out most threateningly, notwithstanding the increased duty placed by the Commonwealth Government upon imported bananas during the year—an increase, it may be mentioned, which was granted at the request of the Fruitgrowers' Conference, held in Queensland a year ago. In our own experience the percentages of over-ripe, or prematurely ripened, or softened bananas in almost every consignment, not only increase the price, and consequently restrict the purchasing of this fruit, but dishearten the grower in Queensland, as well as cause him to imagine the inspectors are unduly severe in rejecting the produce at this end. Ten per cent. is not an infrequent quantity of rejects, and at certain periods of the year even 30 per cent. and 40 per cent. have been found rotten or softened beyond recovery on arrival at Port Adelaide.

“The dissatisfaction in respect to the European trade found expression in a request for the installing of self-registering thermometers in all cargoes of export fruit.

“It would appear as if the consummation of this wish may possibly give some direct evidence of the fluctuations of temperature permitted in the insulated holds during the voyage, but granted these instruments are adopted, there are yet many difficulties. In the discussion upon this subject the recapitulation of experience by members of the Conference proved abundantly that cargoes of fruit—even as tender as William's Bon Chretien pears—can be safely carried to Europe, and it was pointed out to the Conference that until redress for losses sustained by shippers through the lack of care on the voyage was made readily obtainable in Australian courts of law, the shipping companies would doubtless proceed along the lines followed hitherto.

“In my opinion the best assistance the Commonwealth can render the fruit-exporting industry in this connection lies in the direction of protecting the shipper against himself by forbidding the export of any fruit deemed through any cause unfit for the voyage, and at the same time undertaking to compel the companies trading to Commonwealth ports observing such care of the fruit during transport as modern refrigeration has proved to be possible. Unless something of this sort can be done, the whole of the fruit shippers throughout the Commonwealth must needs unite to fight for fair treatment, or the industry will languish. Assuming any such action be taken, freights may rise; but better higher freights and safe carriage than low freights and frequent losses.

THE FRUITGROWER AND THE TARIFF.

"The oppressive character of the tariff as it affects the fruitgrower came in for much condemnation, and, like all other sections of the community, these delegates considered they should be relieved of such burdens. It is not for me to question these conclusions, but subsequent discussions in relation to imported lemons and the recalling of the action of the Conference last year over the bananas question raised a suspicion of inconsistency.

"There was, however, in the discussions upon trade with other parts, a strongly-expressed desire to reciprocate with Canada and the United States, from whence imports of apples are now becoming a regular and increasing item of trade. It was complained that the U.S.A. tariff was decidedly against a return trade on an even footing, but the possibilities on both sides were good, owing to the diverse seasons existing in the two countries. To foster this trade a motion requesting the Commonwealth Government to put up an attractive exhibit at the proposed Panama Exposition was carried unanimously.

SECONDHAND CASES.

"The use of secondhand fruit cases in the inter-State trade revealed a diversity of opinions, apparently based on how it suited the interests of the different States. The delegates from Tasmania and Queensland—the principal case timber-producing States—strongly deprecated the use of secondhand cases, and on a vote the motion in favor of their use secured only seven against five votes.

NOMENCLATURE OF FRUIT.

"The correct nomenclature of fruit, more especially in leading lines of export, such as apples and pears, received some attention, and it was resolved to form a pomological committee in each State, consisting of two fruitgrowers elected—not by their associations, but by the dominant association—and a State official to attempt to correct the confusion now existing. One can foresee a long road ahead of the adoption of any such a committee's conclusions unless some legal status can be given its decisions—a result discussed and discounted by some of the delegates.

"The existing anomalies regarding the naming of the export varieties of apples and pears are not numerous, and the officials present sought to bring the matter into active operation whilst the Conference sat; and to this end the fruit section of the Department of Agriculture in Sydney, at considerable trouble, brought before the Conference a large and well-preserved collection of cool-stored fruits, of apple and pear, but the Conference had spent its energies largely in talk, the question was shelved, and an opportunity lost for at least a year.

SPRAYING.

"The control of spraying materials by the various State Governments was urged on the lines of actual applications of all reputed remedies for plant diseases as against chemical tests, and without an adequate knowledge of the time and expense the motion really involved, or the difficulties to be surmounted, by a vote of seven to six, it was resolved the various State Governments should be asked to test every 'cure all' for plant troubles brought forward by all and sundry, and pronounce upon the same with the forces of the law.

STATE CONTROL OF FRUIT EXPORTS.

"The question of State control of fruit exports was brought forward and vigorously discussed. By the casting vote of the Chairman it was thrown aside as something not even safe to be entrusted to the judgment of the growers' associations in any State. The fact that this course was most strongly suggested by delegates who had great personal interests to serve in keeping the matter out of Government control, and at the same time had no actual experience of what a Government department can do for the producer, must 'give us pause' for reflection before agreeing.

OTHER QUESTIONS.

"Other matters dealt with consisted of affirming resolutions of the Conference of last year respecting standard fruit cases, requesting the State Governments to convene a conference of refrigerating experts to advise on the best conditions to secure safe oversea carriage of fruit, urging the uniformity of railway gauges, and the use of cool cars on State railways for the inter-State transport of fruit, the compulsory registration of nurseries, and the encouragement of all reasonable means of securing fruit to the public at a cheaper rate.

CONCLUSION.

"Through the courtesy of the New South Wales Fruitgrowers' Associations I had an opportunity of visiting, in company with other delegates, the districts of Paramatta, Dural, Galston, Glenorie, Carlingford, and Epping, and inspecting many of the fine citrus orchards situate there. The Government of New South Wales also afforded the delegates and visitors an opportunity of visiting the Hawkesbury Agricultural College, at Richmond, and observing the various horticultural and other operations carried on at the institut on.'

KYBYBOLITE EXPERIMENTAL FARM.

FARMERS' VISIT OF INSPECTION.

In view of the large extent of country where similar problems of drainage and sweetening the soil have to be solved, particular interest attaches to the work being done under the superintendence of Mr. W. J. Colebatch, B.Sc., at the Kybybolite Experimental Farm. That this is generally recognised was demonstrated on Friday, November 22nd, when nearly 200 farmers, some of whom had journeyed by rail nearly 100 miles and others had driven nearly 50 miles, attended at the farm to inspect the crops and the operations generally. Included among the other visitors were the Minister of Agriculture (Hon. T. Pascoe, M.L.C.), the Director of Agriculture (Mr. Wm. Lowrie, M.A., B.Sc.), the Horticultural Expert (Mr. G. Quinn), the Poultry Expert (Mr. D. F. Laurie), and the Director of Agriculture in Southern Rhodesia (Dr. E. A. Nobbs). Copies of some "Notes and Comments" upon the crops in the various fields, the treatment of the land, and the nature of the experiments, which had been prepared by Mr. Colebatch, were distributed prior to the inspection, and proved of material assistance in following his remarks during the tour of the farm.

PREPARATION AND DISPOSAL OF LAND.

It was pointed out that during the two years since the previous farmers' day, the line of progress had lain chiefly in the direction of more thorough and extended surface drainage, and in the acquirement of more definite information relatively to the methods of cultivation best suited to the district, and the proper times to carry them out. Of the 20 odd paddocks on the home farm there were only three comparatively small ones sufficiently free from timber to render possible their use for continuous experiments. One of these was otherwise unsuitable, and one has been surveyed and fenced off into blocks of approximately half an acre, to be utilised for experiments to test the value of different methods of fallowing. Clearing and burning had been conducted persistently, and a start had been made with the netting of the boundary lines. Many miles of new drains had been excavated, and water had been provided in several paddocks previously dry. A capacious implement-shed had been erected, and in numerous other ways the general equipment of the farm had been improved. An effort had also

been made to begin strains of the best varieties of grains by hand selection from last season's bulk crops. A table, dealing with the general disposal of the land during the present season revealed that, including the Binnum blocks, there are 104 acres of wheat, 123 of oats, 50 of barley, 40 of rye, 33 of pease and beans, 161 of greenfeed, 14 of sown grasses, six of lucerne, 56 of rape and kale, five of mangolds, 57 of sorghum and maize, 145 bare fallow, 12 of orchards, 15 occupied buildings, yards, &c., and 1,451 acres of grass land.

THE SEASON.

From October, 1911, to September, 1912, the district suffered from a want of good soaking rains. The lack of occasional summer and early autumn showers to start the growth on the fallows was a serious drawback, and the late arrival of the ploughing rains brought about a condition of affairs that led to hasty and at times faulty seeding operations. In September the dry weather was broken by a phenomenal fall of 5·83in. The farm drains were all running to their fullest capacity, and in one field the pressure was sufficient to sweep away a bank. Nevertheless the fall did a wonderful amount of good, both to the crops and to the rooted grasses. It brought in its wake a burst of feed which made it difficult to conceive that only a few weeks before all energies had been directed to carting out chaff and straw to save stock from starvation. Since the September downpour some useful showers have fallen.

THE CROPS.

The general opinion was that Mr. Colebatch and his staff are to be congratulated on the condition of the crops, which give promise of heavy returns. The benefit derived through the excavation of the drains was strikingly shown in one of the fields. The heavy downpour in September caused the head drain in this field to burst its banks at one or two points, and the bad effect on the inundated portion of the crop is still clearly observable.

One paddock of Bordier wheat was anticipated by the visitors to average between 18bush. to 20bush. Referring to this field, Mr. Colebatch states—“The soil is not uniform throughout, but on the whole may be classed as good cropping land for this district. The bank next the farm buildings is of a loamy nature and fairly rich, but the low-lying flat on the northern boundary is a stiff, heavy clay, and inclined to be ‘crab-hole.’ Natural drainage is good, and the lay of the land is such that should it be necessary in wet years to provide supplementary channels the work could be accomplished without difficulty. Past History—In the ‘sheep station’ days this field was used as a horse paddock, and so far as can be ascertained it had been down in grass for at least 10 years prior to 1911. In 1910, pasture; 1911, oats, sorghum; 1912, wheat. The oat crop yielded slightly over 35cwts. of hay per acre, and the sorghum, which occupied about 10 acres on the flat, grew a strong healthy plant. About two-thirds of the stubble

was ploughed up in the first week of May, but as the rains held off the work had to be interrupted, and the eastern side was not completed till May 29th. The heavy harrows were used to form the seed bed, which was drilled with $1\frac{1}{4}$ bush. of graded Bordier wheat and 2cwts. of 36/38 mineral superphosphate per acre between 27th and 31st of May. Germination and early growth were satisfactory, particularly on that portion that carried the summer crop last year. This fact accords with our previous experience on this farm as to the stimulating influence of intertillage on succeeding cereals, even when the summer crop has been a heavy and exhausting one. The plant tillered out well and appeared to suffer very little check from the continuous August frosts. In August Cape weed and other rubbish began to appear on the bank, and an effort was made to keep them down by frequent and heavy harrowing, but without much success. The autumn was too dry to admit of adequate weed-destroying cultivation, and consequently a certain amount of rubbish in the bottom of a late tillering variety was to be expected. The whole field was harrowed and cross-harrowed in August, and a marked improvement in the rate of growth soon became apparent. Bordier wheat ripens about a fortnight later than Federation, and, owing to its extensive root system, it is enabled to withstand summer droughts better than the earlier varieties. Last season it yielded 19bush. 2lbs. per acre, despite the fact that less than 80 points of rain were registered during October, November, and the first week of December."

Some of the oats have thriven splendidly, and one plot was predicted to return about 3 tons of hay to the acre. Mr. Colebatch is fairly confident that this crop will establish a record for the farm. Varieties of wheat being tried are Yandillah King, Lott's, Majestic, Bayah, White Tuscan (northern seed), Dart's Imperial, White Tuscan (southern seed), Huguenot, Federation, Gallant, Clubhead, Talavera, Marshall's No. 3, Baroota Wonder, Golden Drop, Bordier, Treasurer, Tardent's Blue, and Sensation. The following experiments have been planned with great thoroughness, and the results recorded should be of material help to the farmers in these districts. Comprehensive manurial tests are proceeding, and the following varieties of mangolds are being grown:—Champion, Yellow Globe, Red Globe, Giant Half Sugar, Golden Yellow Mammoth, Yellow Intermediate, Long Red, Mammoth Long Red, and Golden Tankard.

FODDERS.

Among the introduced fodder grasses are ordinary Italian and Western wolph's rye grass. The latter is an improved type. Germination was pleasing, but subsequently weeds choked out a good deal. In the struggle for supremacy Westernwolph's proved to be capable of stronger and more vigorous growth in the early stages. At present both plots make a pretty picture, and Westernwolph's appears to rather better advantage than the

ordinary kind. In view of the high price of Westernwolt's seed it is proposed, if the stripper can be suitably adjusted, to gather the seed for future sowings. The fattening qualities of the rye was shown by the splendid condition of a small flock of English Leicesters depasturing in the field.

The conclusions arrived at by Mr. Colebatch, as a result of tests to ascertain the relative merits of different mixtures for early greenfeed, may be summed up as follows:—In the present state of the soils it is not an economical practice to sow tares at the existing price of seed in admixture with cereals for early greenfeed. Rye is without doubt the earliest of all cereals, and it appears to suit the soils of the district. It would seem, however, that the feeding down of rye which it is intended to let stand for grain, is not altogether safe. The second growth tends to come up very spindley, and to develop short, badly filled ears, and shrunken grain. For early spring feed oats appear to be the best cereal to sow at Kybybolite. They stand the cold, wet winter better than barley, and come away quicker in the spring if they have been sown early. Berseem (Egyptian clover) is apparently not suited to the district for autumn sowing, and Mr. Colebatch believes it would have a much better chance in the South-East if sown about the end of July or early in August. Rape and mustard have not shown themselves to be reliable when early sown in dry seasons. Mr. Colebatch considers that the best practice in the district, when winter and spring feeding are the objective, is to sow from 2½ bush. to 3 bush. of a mixture of equal parts of rye and Algerian oats.

DRAINAGE.

Until the last couple of years, which have been exceptionally dry, the great problem at Kybybolite has been to dispose of the surplus water on the land. The extensive system of drains and water furrows has undoubtedly had beneficial effects, but though Mr. Colebatch is confident that he is working on right lines, he is the first to admit that it requires a wet season to put the system to a thorough test. It is particularly interesting to note that whereas formerly it cost 3s. 6d. a chain to make the drains by manual labor, to-day, by the use of a ditching machine, the work can be done rapidly and efficiently at 6d. a chain.

POULTRY STATION AND ORCHARD.

Two features of the farm which attracted a lot of keen interest were the orchard, planted four years ago, and the poultry station. The orchard, which is being conducted on commercial lines, comprises principally apple trees. The growth made has not been particularly rapid, but the trees are fruiting admirably.

Throughout the day Messrs. Colebatch, Quinn, and Laurie were busily engaged in answering questions, and the evident desire on the part of the visitors to gain information on the various operations was the subject of much favorable comment from Dr. Nobbs.

THE SPEECHES.

At the conclusion of afternoon tea the Minister of Agriculture, addressing the visitors, said it was very gratifying to himself, the Director, and Mr. Colebatch to see so many present that day, and to note the keen interest which they had taken in the work being carried out on the farm. The educational influence and value of an inspection by practical farmers of the diversified methods which had been adopted by Mr. Colebatch could never be tabulated, but its worth would be shown in future years by improved practices and successes. When, as they found that day, the best men in the South-East were willing to sacrifice a day from their farms and travel long distances in order to benefit by the exchange of ideas with each other and from what they saw of the work on the farm, it enabled one to look forward with confidence to further progress in the practice of agriculture in South Australia. It was their pleasure to have with them Dr. Nobbs, Director of Agriculture in Southern Rhodesia, and he asked that gentleman to address them. (Applause.)

Dr. Nobbs said that he had come to South Australia, not to make speeches but to learn. Necessarily, this State was, as regarded modern and scientific methods of agriculture, at a more advanced stage than was the country he represented; and, indeed, he had long known that in that respect South Australian farmers were in the front rank in Australia. The reason for that was apparent that day. He had come there to learn and he had found that the agriculturists here were on a similar errand. He considered that large gathering a notable assemblage, as it showed the high value South Australian farmers placed on scientific methods of agriculture. They realised that an experimental station, such as Kybybolite, existed for their benefit, and were prepared to take advantage of all the lessons that might be gained from it. The number which had attended the inspection of the farm and the keen and intelligent interest they had taken in its various operations had been a revelation to him. With that desire to progress prevalent among the farmers South Australia was bound to go ahead. (Applause.) He desired to take the opportunity of expressing his thanks to the Government and the Director of Agriculture for the facilities they had afforded him during his stay in this State.

Mr. Wedd (Mount Gambier) proposed a vote of thanks to the Minister, the Director, and Mr. Colebatch for their kindness in having given them the opportunity to inspect the farm and also for entertaining them so well. In connection with the latter their thanks were particularly due to Mrs. Colebatch. Mr. Colebatch had had an up-hill fight to bring the farm up to the condition in which they saw it that day. The land was not first-class, but the crops were equal to any that could be found in the Mount Gambier district. A few months ago when he had been on the farm he wondered how the trouble

caused by the sorrel would be overcome, but the result was a great credit to Mr. Colebatch and all concerned.

The vote, which was seconded by Mr. Wright (Naracoorte) and supported by Messrs. Stanton (Bordertown), I. Williams (Penola), and Bradley (Kybybolite), was carried by acclamation.

The Director of Agriculture, in responding, said the benefit that accrued to the State from an experimental farm, such as Kybybolite, was not measured by the money return from the land comprising the farm, but it came from the knowledge gained by the farmers generally as a result of the experiments carried out. He congratulated Mr. Colebatch alike on the keen interest taken in his work, on the condition of his crops, and the results of his operations generally.

Mr. Colebatch said he was very glad that so many had attended. With regard to drainage, he believed he was working on right lines. Some had said to him : " Oh, it's all right this year, but you wait till a wet season comes." Well, he also wanted a wet season, so that the work done might be thoroughly tested. He did not say he was out of the wood yet, but he was satisfied he was working on right lines, and only wanted to perfect the system of drainage. Credit for the work they had seen rested with the employes on the farm. He hoped if they came to the farm on some future occasion in a wet season to be able to show them as good crops as they had seen that day. (Applause.)

A HARVEST FIELD.

APPLE—ESOPUS SPITZENBURGH.

Size—Medium to large, good specimens measure $3\frac{1}{4}$ in. wide by 3 in. long. *Shape*—Oblong and tapering roundly and evenly to the eye end. *Skin*—Smooth, nearly covered with rich lively red, dotted with distinct fawn russet dots. On the shaded side, or when grown in shade, the skin has a yellowish ground with streaks and broken stripes of red. *Eye*—Small and closed, set in a moderately deep basin with undulating dull yellow-colored sides. *Stamens*—Median, tube conical. *Stalk*—Slender, from $\frac{3}{4}$ in. to 1 in. long, clubbed at end, set in a wide deep cavity which bulges inwards on one side. The skin of this cavity has a dull yellowish tint, which extends in irregular flakes or streaks out over its rim. *Flesh*—Yellow, crisp, firm, with juice of a distinctly delicious flavor. *Seed cells*—Ovate, axile, slit.

TREE.

Habit—Upright when young, producing long, slender laterals, which tend to pull it down after fruiting sets in. The bark of the young green lateral is white and downy, and thickly strewn with fawn dots changing as it matures to a clear greenish-grey tint, with the dots still prominent. The bark on old limbs tends to become reddish-brown. The leaf is large, evenly serrated, elliptical, dark-green in color, and downy beneath, each leaf stalk possessing two leafy stipules at its base. If shaped when young the tree requires very little pruning afterwards. *Liability to disease*—The fruits are very subject to bitter pit, and to fungus diseases to a lesser degree. The tree tends to crop on alternate years. *Climatic and soil conditions*—The variety has not been widely planted in this State, so that little is at present known of its special requirements. It appears to do best in those parts of the Mount Lofty

A. Vaughan, Govt. Photolitho

ESOPUS SPITZENBURG APPLE.

Ranges where the red gum trees are found naturally, such as around Belair and Coromandel Valley, and where the soils are not too strong. Fair specimens have been produced in the South-East. It may, therefore, be classed as a "cool country" variety. Its season locally is from April-July. *Origin*—Esopus, a famous apple district on the Hudson River, U.S.A., formerly settled by the Low Dutch. In America it ranks as a standard apple alongside Newtown Pippin. Its synonyms are Aesopus Spitzenburgh—True Spitzenburgh.

A DESTRUCTIVE ROOT MITE.

Mr. Quinn, Horticultural Instructor, writes:—On page 407 of *Journal of Agriculture*, November, 1912, a paragraph respecting this pest was printed, conveying the opinions of Mr. Lea (Entomologist at the South Australian Museum) respecting its identity and characteristics. This came under the notice of Mr. C. French, jun., Acting Government Entomologist in Victoria, who kindly wrote me to the effect that—"This mite is very common in Victoria, where it attacks vegetables and garden plants. I would advise you to give the 'manurial insecticide' a trial against it, as we have had splendid results with this chemical in Victoria." In reply to further inquiries, Mr. French forwarded a leaflet respecting this compound, which is obtainable from Morris & Meeks, Ironmongers, Bourke Street, Melbourne, the prices being quoted at the rates of 32s. per hundredweight for 28lbs., down to 15s. per hundredweight for one ton lots. This might be worthy of a trial by those troubled with this "bulb mite" referred to (*Rhizoglyphus echinopus*). The powder is dibbled in about 3in. or 4in. away from the plants and about as deep as the roots are found. It may also be chopped in with a hoe. About $\frac{1}{2}$ oz. is dibbled into each hole.

DEFOLIATED ORANGE TREES.

By GEO. QUINN, Horticultural Instructor.

At the present time many of the orange trees in a large number of the citrus plantations upon the plains of Adelaide present a very dilapidated appearance through the denudation of leaves and the presence of dry brushwood protruding from the tops. As a general principle this applies to the trees of mature age, and to a lesser degree to those planted only a couple of seasons ago. Those trees rising from three years to seven years old are, as a rule, in much better condition than those older or younger. This decadent appearance in the commercial citrus groves is so general along the valley of the Torrens that I have been frequently consulted of late by growers respecting its possible cause and how to mitigate the injury sustained. After examining a great number of trees growing in many orangeries I am of the opinion that it is due to a combination of circumstances which, fortunately, do not often arise. These are as follows:--The winter of 1911, when the orange trees matured a very heavy crop, was one of very deficient rainfall, only 15.99in. falling for the whole year. For the first half of 1912, 7.64in. fell, the season proving cool but dry late into the autumn. The effect of this upon the trees was productive of a slowly-ripened growth of a somewhat stunted character. Early in the spring the trees started into growth and produced a profusion of bloom scarcely equalled within my recollection. Simultaneously with this start to bloom the old foliage began to fall freely, and by the time the white sheet of blossom had gone from the trees they presented a broom-like top of dead or drying twigs. At the present the twigs which have survived are crowded with embryo oranges, many of which are falling, or must fall, infertile.

I am strongly of the opinion this condition has resulted from lack of moisture in the soil during the summer of 1911 and autumn of this year. During that dry period the useful reserve of moisture usually present in the subsoil became exhausted, and the very partial wetting of the soil by irrigation applied under ordinary methods did not make up for the deficiency.

Anyone who has had occasion to carefully break up an irrigation trench or ring shortly after a tree has received what has been considered a good drink, must have been surprised to note what a short distance the moisture had spread through the soil, either in a lateral or downward direction.

Now, the sublayers of soil in a plantation occupied by fully-grown citrus trees are known to be permeated by a complete network of roots. Further,

the outer fringe of these is usually composed of the most recently formed and active fibres. When trees are watered individually by the ring or basin methods a great portion of these outer extensions of the root system would be spread beyond the soakage radius of the irrigation water, and must in

Orange Tree in need of Renovation.

consequence suffer most. Knowing that there is a sympathetic extension going on in the branch and root systems of a tree, it would appear reasonable to assume that the above explanation of the decline of the roots can account for the dying back of the terminals of the branches. This can be proved to

demonstration with any plant grown in a pot, from which it may be removed and the condition of the roots closely ascertained. The gardener who finds his hard-wooded potplants going off at the extremities of the branches almost invariably realises that the terminal absorbing rootlets have decayed, whether

Pruning Suggested for Renovation of Previous Tree.

it be through lack of water or too much moisture due to interrupted drainage. The method of resuscitation usually adopted in such cases is to remove the plant from the pot, scrape or wash away the stagnant or dried soil, carefully prune away the dead ends of the roots, cut back the top in proportion

to where the wood and bark are healthy, and then replace the plant in probably a smaller and cleaner well-drained pot, embedding its roots in sweet, new soil of only a moderately rich consistency. After it has made a good start to form fresh roots and shoots it may be repotted or topdressed with richer soil, or receive doses of liquid manure from time to time.

This procedure indicates to my mind a way to renovate our citrus trees. If the bark on the branches be carefully examined, it will be noted that

How the Tree in the Previous Plate appeared a few months later

many erstwhile dormant buds are starting into activity below the position of the dead twigs. These usually hint at where to amputate the declining twigs or branches. Sometimes lively shoots are emerging from limbs a closer examination of which shows dead bark on one side below such young growths. In such cases cut below these first shoots to where the bark is sound all around the branch. If no bursting buds are showing upon the branches, test the bark with the knife for an indication of free, healthy sap beneath, and cut where that is found.

Following up this treatment of the top, the roots must receive encouragement. Unlike the potplant, it is not usually practicable to cut away the dead roots, but the formation of new roots from the sound portions of the old ones may be readily achieved by generously treating the soils above them. This consists of good tillage and frequent irrigating, and— if no organic mulching material be available—breaking up and finely pulverising the soil where the water trenches were made, between each irrigation.

Wherever the trees are showing for young growth and carrying a crop of newly-formed fruit, a little nourishment in the shape of a readily-soluble fertiliser should be given in several small doses over the summer season. A nitrogenous compound is necessary to assist the formation of foliage and shoots, and to this could be added phosphatic and potassic fertilisers wherever a crop is on the tree. From 1lb. to 1½lbs. of nitrate of soda or sulphate of ammonia, 1lb. of sulphate of potash, and 3lbs. superphosphate would form a good ration per tree. If the soil be sweet and possessed of lime, the three last-named could be mixed together and applied so. The method suggested is to divide the combined dressing into three parts and apply one-third at each irrigation. The mixture could be sown into the irrigation rings around each tree as they were filled, beginning, of course, at the lowest point of the flow as each ring is finally shut off from the water head. The ammonia and potash would dissolve at once and soak in with the percolating water, whilst what remains of the superphosphate, though less rapid in dissolving, could be mixed into the soil when pulverising the rings a day or two later. Such a process has been found to feed the trees and help them to carry their crops without exhaustion. Should the summer prove dry, it would be a wise precaution to enlarge the area of the irrigation rings around each tree at each *alternate* watering, as this would tend to obviate to a great extent the formation of those dry zones to which this decline has been mainly attributed.

It may be mentioned, in passing, that in 1897 a precisely similar decline occurred in our citrus trees. In 1896 the rainfall was 15·17in., and in 1897 the ground was not soaked until June, and the year's fall only totalled 15·42in. On page 420 of this *Journal* for December of that year I gave a description of the condition of the trees then which might be read with interest by anyone who perhaps views the present situation with apprehension.

The plates given herein were taken at that time, and are typical of the process of renovation suggested herein.

FARM ANIMALS.

HEREDITARY UNSOUNDNESS—(*Continued*).

By C. A. LOXTON, G.M.V.C., Assistant Government Veterinary Surgeon.

BOG-SPAVIN AND THOROUGHPIN.

Both these diseases affect the synovial (lubricating) structures of the hock. The hock joint, in common with other true joints, is provided with a capsular ligament lined by a membrane which secretes synovia or "joint oil." Where the tendons of muscles pass over a joint they are bound down by fibrous sheaths and lubricated by the same fluid.

When this synovial fluid, or "joint oil," is secreted in an abnormal and excessive amount, it distends the capsule and forms an elastic fluctuating swelling at a point where there is least resistance to the pressure.

This condition affecting the true hock joint constitutes bog-spavin, and when affecting the bursa of one of the great tendons passing over the hock is called thoroughpin.

Both these diseases are often associated and are most common in draught horses, especially in young animals just put to work, and in those being prepared for show. Hereditary predisposition is a very important factor, as is also defective conformation of the hock, which is itself an hereditary defect. In this connection straight hocks are especially to be noted.

Bog-spavin, as already described, is a distension of the capsule of the true hock joint with synovia. It takes the form of a fluctuating, more or less soft, swelling, chiefly in front and towards the inside of the joint. The extent of the swelling is variable, as is also the degree of lameness caused by the trouble. In most cases the lameness is not pronounced, amounting to slight stiffness at the joint; in others there is acute inflammation, accompanied by severe lameness.

Thoroughpin is a synovial swelling, similar in character to bog-spavin, and situated at the upper and posterior point of the hock. The swelling is ovoid in form and may appear on one side only, but more frequently on both. Pressure on one side increases the size of the swelling on the other side, which gives the name thoroughpin to the disease.

CURB.

This unsoundness forms an enlargement at the back of the hock, a few inches below the point. The swelling is best seen by viewing the leg in profile, when the normal straight line from the point of the hock to the fetlock will be seen to have a convexity at the seat of curb—about 3in. or 4in. below the point of the hock.

Curb is most common in light horses, and consists in an inflammatory thickening of an important ligament attached to the posterior surface of the bones of the hock and to the head of the cannon bone behind. Horses with "tied in" and those with sickle-shaped or curby hocks are particularly prone to the disease.

True curb must be distinguished from that defect of conformation known as "curby" hocks, which, however, are predisposed to curb. Heredity is also a predisposing cause.

In the early stages of the disease lameness is present, with local heat and pain on pressure. As a rule lameness disappears in a week or two, except in young horses, but the swelling remains as a permanent blemish.

POULTRY NOTES.

By D. F. LAURIE, Government Poultry Expert and Lecturer.

CO-OPERATION AMONG POULTRY BREEDERS.

As a rule poultry breeders, especially those who live in the country, complain that they are compelled to accept whatever prices the collectors and storekeepers choose to pay. They also know that even where there is competition they (the breeders) pay the middleman his profit. In some localities, and under certain conditions, the collectors and hawkers are valuable aids in collecting and marketing produce. There are many localities, however, where breeders are numerous, and where good market facilities exist. It would be to the advantage of breeders to co-operate for their mutual benefit. Many breeders keep only a few fowls, and even in the glut season do not gather sufficient eggs to fill a case. Here co-operation would be a boon, for the following reasons :—

1. Eggs should be gathered daily, and sent to market twice a week in cold weather and three times a week in hot weather.

2. The smallest egg crate which it is profitable to use contains 25 dozen eggs. Only a large breeder could use such large cases for forwarding eggs to Adelaide.

3. In order to obtain the best results, and to minimise breakage, it is advisable to use modern egg crates. These contain, when full, 25 dozen, and are strongly made, fitted with cardboard fillers, boards and wood wool packing material. They are accepted on the railways as weighing, when full, half a hundredweight. The lid is reversible, and can be branded with the owner's name and address on one side, the name of the Adelaide merchant on the reverse. The lid is fixed so that it can be attached or removed quickly ; no nails are required.

4. If the eggs could be delivered at a given point, where they would be received and packed by some person appointed, then uniformity can be attained and sufficient eggs obtained to fill one or more cases without delay.

5. Merchants are beginning to pay more attention to quality, and the absolutely fresh egg is gaining recognition as the only one which should be sold and bought at full rates. Unfortunately the day has not yet come when the sale of stale eggs is prohibited. Still, it is satisfactory to learn that stale eggs, in many cases, are now sold as such. Co-operation, that is the bulking and prompt marketing of the poultry products of a number of breeders, will bring about improvement in this direction.

NARACOOORTE POULTRY ASSOCIATION.

The poultry breeders of Naracoorte some time ago decided to form a local poultry association. When I was first communicated with upon the subject I was under the impression that an ordinary association for exhibiting show poultry was intended. It was gratifying to learn, however, that something of more value to the industry was contemplated. An association, on co-operative lines, was formed, and up to the present the members are well satisfied with results, and are working to gain further benefits.

The following are the principal rules adopted by the Naracoorte association, and it is to be hoped that they will be adopted by associations to be formed in other localities :—

1. The association shall be called "The Naracoorte Poultry Association."
2. The objects of the association are, viz.—(a) To facilitate the marketing of eggs. (b) To encourage poultry breeders to pursue a more thorough method of egg-production. (c) To improve the industry in every branch.
3. The officers of the association shall consist of president, vice-president, committee comprised of four (4) members, secretary and treasurer (to be a member of the association).
4. The affairs of the association shall be managed by a committee consisting of the president and four (4) committeemen, to be elected at the annual meeting. Three (3) members to form a quorum.
5. The subscription to the association shall be two shillings and sixpence (2s. 6d.) per annum.
6. The duties of the secretary shall be—(a) To receive all eggs, pack and dispatch them to the market. (b) To attend to all clerical work in connection with the association.
7. The secretary shall receive as salary from the association one half-penny per dozen on all eggs marketed.
8. (a) All eggs delivered by the members must reach the secretary clean and graded. (b) All eggs excepting the undersized ones must be stamped. (c) From the first day of November until the last day of April, all eggs must be infertile. (d) Members shall accept the prices obtained for eggs, less the deductions made for marketing expenses.
9. The president or the secretary shall at any time visit the poultry yards of any members, for the purpose of seeing that rule No. 8 (c) is being strictly observed.
10. All egg cases shall become the property of the association.
11. Any member resigning or being dismissed from the association shall forfeit his or her entrance fee.
12. All fractions in connection with the sale of each consignment shall be devoted to the funds of the association, and if a surplus exists at the end of the year, a bonus shall be declared to members.
13. The association shall purchase stamps, and will deliver same to members at cost price.

14. No non-member shall be allowed to forward eggs through this association.

A GOOD EXAMPLE.

On visiting various parts of the country I find many cases where half a dozen farmers live sufficiently close to one another to justify the formation of a similar association. Not only are eggs dealt with, but also live poultry. Poultry of all sorts has, during the last few years, realised excellent prices in Adelaide. In most country districts the local prices are low, and out of all proportion to the Adelaide equivalent. I met many farmers who would have been glad of the extra penny or penny halfpenny per dozen that eggs dealt with on the co-operative plan would have realised. There is evidence in every direction that farmers and others are attracted by the greatly improved prices eggs and poultry are now realising. The uncertainties of seasons were for a time overlooked, but recent events have accentuated the value of poultry, and many have resolved to breed on a fairly liberal scale, so that, at any rate, there shall be some revenue from the farm. Without rain you cannot grow crops, but as long as you have water for your fowls to drink they will thrive under any degree of drought. This is well known to most of the older generation of farmers.

MORE INFORMATION.

Energetic readers are informed that the Poultry Expert will be very pleased to give any information required, and will do his utmost to assist in the formation of any projected associations. It may be pointed out that these associations are in no way State institutions. The end in view is the better and more profitable marketing of produce. The preliminary expenses are small, and include a stamp for each member and the requisite number of egg crates. Mr. W. G. Haynes, of Naracoorte, the secretary of the local association, will, I am sure, reply to any letters if a stamp for reply is enclosed. I recently received an invitation to lecture before the Naracoorte Association, and was delighted with the keen audience, who evinced every desire to keep abreast of the times as regards breeding and marketing methods. If invited, I shall be pleased to address other associations, either with a view to assisting in their formation, or of suggesting improved methods of breeding, feeding, &c., as applied to poultry.

OPERATIONS FOR DECEMBER.

The unusually cool weather experienced in November has been favorable to the growth of strong chickens, &c. The frequent cold snaps and periods of wet, rough weather, however, have in some localities caused great mortality among the chickens, especially the late hatched ones. The experience of a number of breeders this year has strengthened a long held conviction that very early hatching is desirable. Autumn-hatched chickens have done well. The cockerels have realised excellent prices as table birds, and on all hands we see fine flocks of autumn-hatched pullets in full lay.

On some large poultry plants the method adopted is to hatch all the stock at a given date. I hear of one Victorian establishment where only one hatch was arranged for. Sufficient incubators to provide for a hatch of 2,000 chickens in one batch were filled. This method could not be generally adopted, and I am not sure that it is advisable except in special circumstances.

THE BREEDING STOCK.

As a rule, on the termination of the breeding season, the valuable breeding stock is neglected. No greater mistake could be made. Any that are to be discarded should be culled out and disposed of. Progressive breeders must make room for improved stock and thus annually have old stock, but valuable for their breeding, which can be disposed of at moderate prices. Beginners are, as a rule, glad to get such birds, for, although they will not lay as many eggs as younger birds, are of good breeding, and preferable as breeders to pullets and other immature birds.

The breeding hens to be used again next season should be looked over and examined as to condition. Vermin should be destroyed, and scaly leg treated with soft soap. The male birds should be removed and penned as far away from the hens as possible. They should also be carefully examined and treated as necessary. Male birds to be used in the breeding pens next season should be got into good condition, otherwise the progeny will be poor.

MOULTING.

Towards the end of the month the annual moult may begin in some localities. More generous feeding will generally assist the process. Linseed boiled to a jelly and mixed in moderation with the morning mash will prove valuable. Its use will, as a rule, affect egg production, but it will also act upon the feathers. The additional fat content will act on the old feathers in the direction of assisting the process of casting. The special proteins will assist the formation of the new feathers.

Sweep up all cast feathers and burn them. They are unsightly and may cause feather eating. Chickens often contract a bad habit of eating the cast off feathers which lie about the runs. The consequence is that impaction of the crop is frequent.

As the breeding hens come through their moult they should be penned ready for autumn breeding. If a few pens can be put together in March or April there will be some fine early chickens. Various statements have been made against autumn hatching; as a rule by persons who have not had practical experience. Quite a number of large breeders are following the advice previously given on this point, and already they have proved its great value. At the poultry stations the autumn-hatched pullets have been invaluable as layers and for use as breeding stock later on. They have a long period of growth in cool weather.

THE YOUNG STOCK.

Push forward the surplus cockerels and dispose of them as soon as large and fat enough for sale. Those intended as breeders, whether for sale or otherwise, should not be forced, but should be kept growing and free from vermin. The pullets must be well attended to also. Keep them growing, and do all you can by frequently shifting them from yard to yard to delay egg production until they are well grown. Do not use meat or green bone; these force them to early laying. The result is that the immature pullet is stunted and that she lays small eggs.

INTERNAL PARASITES (WORMS).

There are several species of internal parasites which affect poultry. The round worm is very frequently found. The most common is that known as *heterakis*, of which there are several. Some inhabit the crop and gizzard, others the duodenum, caeca, &c., in the bowels. They vary in length according to species, from one-eighth of an inch to over 3in. in length, are very slender, and generally whitish in color. Chickens, especially those late hatched, become infected. Often the symptoms are looseness of the bowels and a choking sound and running at the nostrils which may be mistaken for roup. The birds become emaciated and have a ravenous appetite. Sometimes the worms may be passed in the excreta.

Treatment.—Fast the birds for 12 hours, allowing water to drink, but no food of any sort. Mix with dry bran and pollard a heaped teaspoonful of the following powder for each 20 adult, or 30 half-grown, or 40 quarter-grown chickens. When thoroughly mixed the bran and pollard, &c., may be moistened to a crumbly mass. Repeat in a fortnight:—

Santonine	1 part	} By weight.
Freshly ground areca nut	7 "	

For a single fowl, give in a bread pill, 7grs., or as much as will lie on a sixpence. The ground in the yards should be well disinfected and then worked over.

HANDLING A SICK BIRD.

It is occasionally necessary to examine a bird or to administer medicine. Place the bird under your left arm so that its weight rests on your lower arm and wrist. The upper part of the arm encircles the wings and legs and prevents flapping and kicking. The left hand is available to hold the head or to open the mandibles (beak). Your right hand is free now for performing an operation, or for administering medicine, whether liquid or as a pill. Pills should be dropped behind the tongue, the beak closed, and the pill then stroked down the gullet.

AUSTRALIAN STOCK IN AMERICA.

It is gratifying to note that in Section 1 of the Laying Competition held at Victoria, British Columbia, the first and second prizes were gained by an Australian bred pen.

EGG-LAYING COMPETITIONS.

TWELVE MONTHS' TEST.

ROSEWORTHY.

[Started April 1st, 1912, and to terminate March 31st, 1913.]

Competitor.	Eggs Laid for Month ended Nov. 30th.	Total Eggs Laid from April 1st, 1912, to Nov. 30th, 1912.

NOTES ON EGG-LAYING COMPETITIONS.

ROSEWORTHY AND KYBYBOLITE POULTRY STATIONS.

REPORT FOR MONTH OF NOVEMBER, 1912.

At this season of the year many things may happen, any of which may make or mar the prospects of record figures. Last year (1911-12) the leading pen, at this time and until the end of the test, was putting up splendid records for the season of the year. This year the leading pen for some time had a substantial lead upon the figures of the winning pen last year, but although the egg yield is good it does not compare with the yield of the winning pen at this period last year. It is yet too early to prophesy. Last year the man in the street forecasted incorrectly. Much depends on when the birds moult and how they come through that process. Sudden changes or very severe heat may wreck the chances of a pen, or even of the whole competition, for good averages. Health—It has been again noted this year that an undue number of the hens have died of trouble connected with the organs of reproduction. This matter was the subject of comment by me in the report of the last competition. My views were not palatable to some people who, apparently, would disguise facts. It is my duty as Poultry Expert, and for the time custodian of the birds in the public tests, to comment on all such features and to issue timely warnings. I have pointed out that certain pens have had more than one case, and that this points to hereditary weakness in the stock. At no time did I infer that this and similar troubles were common among our flocks of poultry. Breeders must desist from measures which tend to force egg production or growth. Many of these troubles are the result of the silly advice given by impractical poultry writers who advise the free and liberal use of cut green bone, and other animal food, all of highly forcing nature. Stock which produces progeny with similar failings is manifestly unsuited, and a change should be made.

ROSEWORTHY.

The Superintendent reports—The present time ends the eighth month of the test and is a period when fluctuations in the laying, alteration in the appearance of the birds, and various other changes may be expected. In fact, it is a time which might be termed critical, as any unseasonable weather or very sudden changes in climatic conditions may result unfavorably to the birds. Some of the birds are at the stage when radical changes in the weather may start an early moult. It will be remembered that nearly all of the birds moulted more or less severely after their arrival here this year, and, therefore, according to the laws of breeding ought not to moult a second time in the period under test, but past experience has shown that it is quite possible to experience a general break up among the layers. This, if not characterised by a heavy general moult, is sufficiently severe to affect the averages, and in many instances to stop the laying altogether. The advent of drier weather conditions with higher temperatures appears to be against further heavy general laying, as totals have shown a tendency to diminish lately. And although, perhaps, not to any great extent, indications point to a lowering in that direction in the future. During the month strong winds have been prevalent, and such conditions do not in any way tend to increase the productiveness of the hens. The average maximum temperature has been 74°, the average minimum 45·4°, with 98·7° and 31° as the highest and lowest readings. Rain fell on eight days, aggregating 1·84in. The general health of the birds is good. I regret having to report six deaths during the month, as follows:—Section 1—Four, apparently from the following causes:—One through liver complaint, one severe attack of dysentery, one through cropbound, one paralysis. Section 3 lost two through oviduct troubles. All the birds but one have been replaced. Broodiness has prevailed as follows:—Section 1, 64; section 4, 105; section 3, eight; total, 177. The production by the three sections for the month was as follows:—Section 1, 10,510; section 2, 2,957; section 3, 2,617; total, 16,084 eggs. The averages per pen were 126·6, 95·3, and 130·8 respectively, while the grand total shows a falling off of 382 eggs as against that of October.

Inter-State Competitors.—The inter-State competitors are holding their own, and have put up fair records. It will be noted their scores for the month of November are of the highest. All the birds are well and in good working condition.

KYBYBOLITE.

The Superintendent reports—The laying for the month was similar to that of last month, making neither improvement nor an appreciable falling off. For the first six months the birds were confined to their houses, which measure 8ft. by 4ft. 6in., and during October and November were allowed the runs attached, which are 30ft. long. No improvement in the scores can be noticed, in fact the best scores were put up during the period of confinement. The feeding has been the same, and the only reason that can be assigned for the lack of improvement in the laying and slight falling off is the changeable weather that we have had. It has been very warm on one day and cold and wintry the next. Possibly the fowls would have laid better if they had been kept in their houses until now, but, when once they are let out, I do not think it advisable to shut them in for a day or so for rough weather, as they do not take kindly to too many changes. The wind has been severe during the month. The maximum temperature was 90° and the minimum 36°. On 20 days wind was registered. Two deaths occurred in section 1 and were due to oviduct troubles; otherwise the birds are all well and healthy in appearance. In section 1 four birds had to be removed for broodiness, while section 2 added 14 to the broody pens.

D. F. LAURIE, Poultry Expert.

DAIRY AND FARM PRODUCE MARKETS.

The General Manager of the Produce Department reports on December 1st :—

BUTTER FACTORY.

The supply of cream received this month has been greatly in excess of the usual quantity for this period of the year, and the generally cool conditions have kept it up to a high standard, so that the quality of the butter has been well maintained.

There has been a slight reduction in prices during the month, present quotations being superfine, 11½d. per lb.; and pure creamery, 10½d. per lb.

A. W. Sandford & Co., Limited, report on December 1st :—

BUTTER.—The splendid general rainfall experienced early in November has had the effect of lengthening the season in butter and cream, though supplies are now on the decrease. The London market weakened considerably and consequently values here receded in sympathy. Best factory and creamery, fresh in prints, sold at from 10½d. to 11½d. per lb.; choice separators and dairies, 10d. to 11d.; store and collectors, 8½d. to 9d.

EGGS.—The market continues firm. Buyers are still operating extensively, values now being 10½d. per dozen for guaranteed new-laid hen; duck, 10½d.

CHEESE.—Prices are not quite so high as a month ago for new made, but matured samples are still very scarce. New made is selling at 6½d. to 7½d. per lb. for large to loaf; matured, 11d. to 1s.

BACON AND HAMS.—The rates ruling here previously have, as mentioned earlier, attracted consignments from other States, and consequently values are weaker. Best factory-cured sides realised 9½d. to 10½d. per lb.; hams, 1s. to 1s. 1d.

HONEY.—The demand continues brisk, all consignments of well-flavored clear extracted meeting with speedy sales at 3½d. per lb.; beeswax, 1s. 3d.

ALMONDS.—The season being about over the only parcels offering are very small ones, but the demand for kernels is good. Quotations—Brandis, 6d.; mixed soft shells, 5½d.; kernels, 1s. 3½d.

LIVE POULTRY.—The month's business in poultry has been very extensive, the facilities now offering for cold storage enabling buyers to secure and put away for Christmas requirements. As a result all quality lots have experienced keen competition, so that good rates have been secured for consignors. Good table roosters are worth 3s. 6d. to 4s. each; plump hens and cockerels, 2s. to 3s.; ducks, from 2s. to 3s.; geese, 4s. 6d. to 6s., according to condition; pigeons, 7d.; turkeys, from 10d. to 1s. 1d. per lb. live weight, for fair to prime table sorts.

POTATOES AND ONIONS.—As expected, prices for potatoes have receded, in fact the drop was a very sharp one. New season's potatoes are finding a market in increasing quantities, the warmer weather having hastened the ripening. Victoria is also offering new season's potatoes, and some W.A. tubers are finding their way to this State. Onions—Values for onions are also very much lower, and the prospect of a heavy crop throughout Australia helps to give the market an easier tendency still. Present quotations—Potatoes, new, £12 to £14 per ton on trucks, Adelaide or Port; onions, Gambiers, £6 to £7 10s. per ton on trucks, Adelaide or Port.

THE WHEAT MARKET.

The continued favorable reports received of the crop outlook in the Argentine and other wheat-growing countries caused, during November, a considerable decline in prices on the London market. This was accentuated towards the end of the month by the improved prospects of a settlement of the war between Turkey and the Balkan States. Prices locally fell in unison, and it is interesting to note that the rate, 3s. 6d., quoted on the 4th instant, corresponds with that ruling on the same date twelve months ago. It has been estimated that the Commonwealth harvest this season will total 81,000,000bush. compared with a little under 72,000,000bush. in 1911-12.

Dealing with the wheat position on October 25th, Beerbohm's states:—"Exports to date this season have been about 3,000,000qrs. larger than in the corresponding period last season, and as this year's world's crop, allowing moderate yields for Australia and Argentina, is a record one, there should be no difficulty in obtaining all the wheat wanted. In the three years ending 1911 the average yield was 437 million quarters, against an average of 392 million quarters in the three years ended 1908. This year's total promises to reach 450 million quarters, or 13 million quarters above the average of the last three years."

On November 1st the same journal reports:—"Crop prospects in some parts of Australia and India are reported to be rather less favorable, whilst too much rain has fallen in Western Buenos Ayres, but so far no serious complaints have been made. There is no particular change in the general situation, but the opinion now appears to be more general that there will be no serious complications in connection with the war in the Near East. If this proves to be correct the principal support of the market will be taken away, and, with the prospects of liberal shipments for some time to come, it may be difficult to maintain prices at their present level unless Argentine and Australian crop prospects deteriorate considerably.

"Shipments last week were again large, and estimating the present week's total at 1,500,000qrs. the total export to Europe, in the three months August to October, have amounted to the large total of 18,435,000qrs., against estimated consumptive requirements of about 16,250,000qrs. (1,250,000qrs. per week). This estimate of 1,250,000qrs. per week is based on total European import requirements of 65,000,000qrs. (after allowing for over 10 % of this year's crop being unfit for human food in the U.K., Germany, Holland and Belgium, and about 5 % in France), made up as follows:—

	Qrs.
United Kingdom	28,000,000
Germany	10,000,000
Italy	7,500,000
Holland and Belgium	9,500,000
France	3,000,000
Other countries.....	7,000,000
Total	65,000,000

Stocks in first hands at the present time only show a moderate increase compared with three months ago, but it is very probable that there has been a fair increase in second hands."

ADVISORY BOARD OF AGRICULTURE.

Dates of Meetings—

December 11th, January 8th, 1913.

THE AGRICULTURAL BUREAU OF SOUTH AUSTRALIA.

Every producer should be a member of the Agricultural Bureau. A postcard to the Department of Agriculture will bring information as to the name and address of the secretary of the nearest Branch.

If the nearest Branch is too far from the reader's home, the opportunity occurs to form a new one. Write to the department for fuller particulars concerning the work of this institution.

REPORTS OF BUREAU MEETINGS.

Edited by GEORGE G. NICHOLLS, Secretary Advisory Board of Agriculture.

UPPER-NORTH DISTRICT.

(PETERSBURG AND NORTHWARD)

Amyton, October 22.

(Average annual rainfall, 11½ in.)

PRESENT.—Messrs. T. O'Donoghue (chair). A. Wallace, S. Thomas, A. J. Phillis, Wm. Gum, T. Ward, E. C. Mills, D. P. Aitken, R. Brown, A. Crisp (Hon. Sec.), and two visitors

WORMS IN HORSES.—Mr. A. Wallace, in a short paper, stated that there were three varieties of tape worms, and seven of round worms found in horses; the former were a rare occurrence, but the latter were both very common and highly injurious. Continuing the paper said—"Those which are so common in horses are small round worms about 1½ to 2 in. long, pointed at both ends, and possessing a small black head. They inhabit the large intestines and the rectum, where they often exist in large numbers. Some of them pass away from time to time in the dung. When in large numbers, their presence will be betrayed by a ravenous appetite on the part of the horse, and a dry, coarse, staring coat, and pot belly. A whitish-yellow mould will be seen around the anus, probably made by worms crushed while passing out. The animal will also rub its limbs, tail, and anus against a post or wire fence. I find the most convenient and effective remedy is the following:—1 dram sulphate of iron, 1 dram tartar emetic, 2 drams linseed meal, mixed, and given as one dose, repeating it morning and night for a week; then give a purgative as follows:—1 oz. spirits of turpentine and 1 pint of raw linseed oil mixed. Sufficient accuracy in fluid measure for anything not violent in its action will be the following:—67 drops, or 1 teaspoonful, equal 1 dram; 8 drams equal 1 oz.; 16 ozs. make 1 pint." Mr. Gum stated that it was necessary to confine horses that were to be drenched, as otherwise it was difficult to determine whether the drench had been effective. Members generally agreed that the cautious administration of spirit of turpentine and linseed oil was a sure and safe remedy for this trouble.

FENCING.—In a short paper on this subject, Mr. T. Ward said a good substantial fence for this district could be made of gum posts set 14 yds. apart, with two T-iron droppers set between. Strainers should be placed not more than six chains apart, and the wiring from the top should be as follows:—First wire top of post, second wire 9 in. down, third 14 in. down, the remaining three being set 6 in. apart; this would make a six-wire fence, 3 ft. 4 in. high, with the bottom wire 5 in. from the ground. The first and second wires should be barbed, the third No. 8, and the remainder should consist of No. 10 gauge. When commencing a fence, it was advisable to put up the first strain, strain the two barbed wires, tie the standards, and then commence the next strain. The four plain wires could then be run through and strained, and the fence completed in this manner. It was a good plan to insert an old bolt in the strainer, against which the strut should be placed. Care should be taken to keep the boring straight, and ¼ in. bits would be found large enough. Posts 5 ft. 2 in. long, placed 22 in. in the ground, would be found large enough; the strainers should be 6 ft. 6 in. in length, and the standards 4 ft. Mr. Brown thought 14 yds. was too far between the posts, and Mr. Wallace advocated ¼ in. holes, because the wires were not so liable then to rust in the posts. Mr. Gum thought the smaller the hole the better.

Coomooroo, October 21.

(Average annual rainfall, 12in.)

PRESENT.—Messrs. Berryman (chair), J. Brown, L. Avery, H. Fisher, C. Phillis, E. Brice, A. Cooke, W. Robertson, R. G. Polden (Hon. Sec.).

FARM IMPLEMENTS.—In a discussion on this subject, Mr. Robertson said that it was a mistake to allow the wheels of implements to become dry of oil. If care were given to this, the life of the implements would be considerably lengthened. Mr. Berryman advised covering the farm implements with boiled oil in preference to paint, and he advised the farmers generally to varnish their own buggies. Mr. Brown mentioned that it was necessary to clean away any old oil from bearings, and carefully remove grease from machinery before putting it away.

WOOL-CLASSING.—Mr. Berryman expressed the view that it was inadvisable to take off greasy and sweaty locks from around the legs of fleeces. He would keep the yellow from the white and silky fleeces, where small clips were being dealt with. The Secretary advised classing wool however small the clip, and recommended the careful skirting of all fleeces. Some of the members did not favor the idea of classing where the small flockowner was concerned.

Mount Remarkable, October 24.

(Average annual rainfall, 27in.)

PRESENT.—Messrs. M. S. Giles (chair), J. McIntosh, L. A. Bauer, W. Oldland, T. H. Casley, E. B. Andrews, E. Mayne, and H. H. Davie (Hon. Sec.).

FALLOWING AND CULTIVATING.—Mr. T. H. Casley read the following paper:—"It is recognised by all that the fallowing system is the only way of successfully farming. No one cares to revert to the old style of cropping the same ground every year without giving it a spell. When the land to be fallowed is selected the farmer should always plough in the opposite direction to that in which it was previously ploughed. There should be no necessity to trust to memory; this should be on record in the programme of previous years. Every farmer should keep an account of his working, as it is very handy to refer to for many purposes. He should also know to what depth he ploughed the land last. I do not believe in always ploughing the land to the same depth, as a hard floor is thus made, and this floor gets almost polished and impervious. In this district the land varies in many respects. I will deal more particularly with the average land. Before commencing to plough, the plough itself should be thoroughly overhauled; because if it does not work properly the after effects are noticed for years. Select a nice level piece of ground. Let the plough down, see that each share fits properly, and that all have the same pitch. Also see that each mouldboard is rigid and set to the proper width. Above all do not spare grease or oil, because both are much cheaper than new parts. In setting out the lands much depends on the size of the plough—the larger the implement the bigger the lands. I do not believe in ploughing all round the paddocks. It would be ridiculous to strike out an 80-yd. land for a three-furrow plough, because the headlands would become so hard by constant walking that it would be a difficult matter to plough them properly. A strike-out should be as straight as possible. The furrow wheel should be lifted to the same height as the depth to which you intend to plough. This precaution is rarely taken by ploughmen in striking out or forming the crown. When once the land is struck out straight care should be taken to keep the work straight. What are known as 'pig-troughs' are caused either by the team not being looked after properly or the furrow horses leaving the furrow. Care should be taken to have a good horse or horses for that purpose. Ploughing of the pig-trough variety leaves large strips of ground unbroken, and becomes a nuisance when cross-working with other implements. The time for fallowing depends on circumstances. It is now understood by all up-to-date farmers that the sooner it is commenced the better. Strength and big implements are essential to success; because if a farmer starts fallowing with a small plough, and rain falls whilst he is ploughing, the land he ploughed first gets very dirty before he has time to start killing the weeds. On most farms the paddocks are not uniform as to condition; there are soft and hard spots alternately. A good ploughman knows that when he strikes a hard patch he should drop the plough a notch or two, and when it is soft he should lift the plough. To ensure success the shares should be kept as sharp as possible. If using cast shares they should be chipped frequently, and plated shares should be kept in proper cutting trim. This does not apply to land that can be ploughed through the whole season with the same set of shares. When the paddock is finished, the headlands should be carefully done. I find it pays well to do a few rounds inside the places where the plough has been lifted, because in some cases the plough is drawn closer to

the fence than in others. It is a mistake to allow horses to run loose on land whilst it is being fallowed, because they roll on the soft ground, and these rolled spots after a shower of rain become very hard. The method of working the fallow depends to a great extent on the nature of the soil. Working should be done before the weeds get a start. The best time to exterminate stinkwort is when the plant is from 2in. to 3in. high. Much depends on the class of implements used for the working of fallowed land. To ensure the quick growth of weeds the fallow should be cross-harrowed as soon as possible after a rain—the harrows thoroughly level, and pulverise the ground. Harrow tines should be kept as sharp as possible, and none should be absent, because missed strips are noticeable later in the season. I advise those farmers who have no stony patches to use the disc implements; but for land that has patches of stones, and hard and soft land, the stump-jump skim plough is best for turning under weeds of all kinds. In these implements, just as is the case with the plough, each furrow should do its work. If not, the implement can be tracked for years after. I find the harrows are about the best implements with which to work the land after the disc or skim ploughs have finished—especially after a rain. Good sharp harrows keep the surface even, and help to a great extent to conserve the moisture, which, in the main, is the principle of good farming. Before seeding I prefer a rain. Wait a few days, then skim and harrow. A light roller used before drilling makes the ground more even and a uniform germination is secured. To be successful, a farmer should pay great attention to the details I have mentioned. It is not the man who puts in the greatest number of acres that is the most successful. I contend that land, if properly worked and kept in good condition to receive the seed, pays far better if, say, 100 acres are well done, than if 300 acres are put in any way: because a nine-bag crop on 100 acres is equal to a three-bag crop on 300 acres in cash value. The advantage is obvious in respect to the ground that has to be traversed, and the wear and tear on implements, use of oil, &c., and the extra work for the teams are all economised. In fact, the man with the 100 acres could have marketed his crop before the other with the 300 acres had finished reaping.”

Wepowie, October 29.

(Average annual rainfall, 12in.)

PRESENT.—MESSRS. J. Crocker (chair), J. Rielly, C. Pearce, C. Knauerhase, M. Irvine, G. Rooke, J. and T. F. Orrock (Hon. Sec.).

CUTTING AND STACKING HAY.—Mr. Irvine read the following paper:—“It is important to cut hay as soon as it is ripe, as over-ripe hay decreases much more in value of straw than it gains in grain. If a crop to be cut has a quantity of oats in it, say half or more, it is a good policy to cut it when the oats are fit, no matter at what stage the wheat is. Besides making good feed for stock the oat kernels will be taken off the land, and it will be noticed the next time the ground is fallowed that the crop is clean, except where stooks have been placed. I prefer stooking up as soon as possible after the binder to keep the sap in the straw. For quick carting a small round stook of about 25 sheaves is a good idea. If the hay is to be left in the field for any length of time long stooks are better; a row up the centre with two sheaves deep on either side. This will not easily damage, as air can pass through it. Since binders have come into use a good amount of hay has been spoiled, or partly so, by being stacked too soon. It is not wise to stack earlier than two weeks after cutting unless under very dry conditions. Take a sheaf from the middle of the stook and a handful of hay from the centre of the sheaf; if, by twisting this round between the hands, you can secure moisture, it is too soon to stack. Wood makes the best dunnage for a stack. Straw also answers very well if a fair amount is used in building. The proper way to build a stack is to place the butts out, keep the centre of the stack full, and spring the walls so that the water from the roof falls clear of the sides. Sheaved straw makes a good covering. Put the sheaves on in the string, butts outward, peg the first row with a wooden peg and knock them up even with a thatcher's bat. The last row at the top should be reversed and have a wire put along the top row of sheaves. A light rail for the other end of the sheaf is all that is necessary to keep this covering on, and it will pay for itself many times over in a wet winter.”

NOXIOUS WEEDS.—Mr. Joseph Rielly dealt with this subject in a paper as follows:—“To the landholder who takes pride in keeping his land free from weeds, the carelessness of his neighbors, who neglect to destroy even the worst kinds, is a continual source of wonder and loss, as while a farmer can keep down the weeds that grow on his own farm he has no defence against the seeds that blow in from his neighbor's. Of course, we have the Noxious Weeds Act, but, unfortunately, it is not as effective as it should be, and many landholders neglect to destroy the weeds on their land. Unfortunately, the careless one

usually has a friend in the council. The average district councillor dearly loves to exercise a little patronage; his plain duty is often forgotten in the desire to do a turn for a friend. Even when the council does attempt to enforce the Act the business part is of necessity left to the clerk. Now, prosecuting people is not a labor of love with the average district clerk. It makes a lot of work for him and it also tends to make him unpopular. One way and another the business is allowed to drag on until it is too late to do anything effectively that year, and one year is very much like another in this respect. If by some extraordinary chance a case does come before the court the defaulter has many things in his favor. There is the wording of the notice, the method of delivery, the time allowed for destruction, and the question of inspection afterwards. The ratepayers, including the men who are careful to keep their own land clean, have to pay all the costs. In the meantime the weeds have gone to seed. The Noxious Weeds Act is good and necessary, but it should be impossible to evade its provisions. As this question chiefly effects the man who is honestly trying to get the best out of his land, *i.e.*, the working farmer, I think it is time that the farmers, through their own Parliament, took a hand in drafting a Bill for an Act that would be workable. I venture to make a few suggestions. In the first place I would do away with the necessity for giving notice, that is personal notice, altogether. A notice in the *Government Gazette*, or posted at certain conspicuous places, as is done under the Prevention of Fires Act, should be sufficient. Then any person who had noxious weeds growing on his land after a certain date, say November 21st, would be liable to prosecution. I would not limit the right of action to the district council, and see no reason why the adjoining landholder should not have that right, as he is the party most interested. If he brought a spiteful or frivolous charge, the court would punish him by making him pay all costs. Local Branches of the Agricultural Bureau should also have the right to deal with cases within their sphere, and it would not be a bad idea if offenders' names were struck off the roll of membership of Branches. I wish to refer briefly to a paper on this subject read before the Port Germein Branch by Mr. Hillam and appearing in the *September Journal*. Mr. Hillam is wrong in stating that star thistle had spread all over the country before being proclaimed a noxious weed. The fact is, it was proclaimed as soon as it got outside the boundaries of a certain sheep run. The small farmers at that time were very anxious to have the weed destroyed, and were continually worrying the council over the matter. Somehow the large estates kept control of the councils, their managers always held a seat, and generally occupied the chair. They openly flouted the Act, and the present state of a large part of country is the direct result of the selfish action of these men. Mr. Hillam thinks it is too late to grapple with the matter and that great hardships would result from drastic measures to enforce compliance with the Act. He also states that many landholders would throw up their land rather than try to clear it of star thistles. The hopeless cry "too late," does not apply in our district, our land is still clean. Even in the worse districts it is possible with closer settlement to keep them in check, and in time to eradicate them altogether. As to hardships, any man who is honestly trying to clear his land is not likely to be troubled by anyone. As to the man who would throw up his land rather than clear it, I think the sooner he throws it up the better; the fact would be proof positive that he had more land than he could use, and there are plenty willing to take it. It would be easier to clear than mallee scrub. In conclusion, let me emphasize the fact that this and similar Acts are framed in the interests of the men on the land, and the landholder who opposes it is standing in his own light. Land is now much too valuable to waste in the production of useless weeds. I have no doubt that every member of this Branch will do his utmost to keep his own plot clean, and whilst thus benefiting himself he will encourage others by his example."

Wilmington, November 20.

(Average annual rainfall, 17½ in.)

PRESENT.—Messrs. A. H. Noll (chair), Slee, Zimmermann, D. and S. George, J. Schuppan, G. Schuppan, Hill, Farrell, McGhee, E. J. Gloede, and B. Jericho (Hon. Sec.).

BREEDING HORSES.—Mr. Farrell contributed the following paper:—"As an adjunct to farming, the breeding of horses is a great help. First, we must decide on what we are going to breed. In my opinion the Clydesdale is the horse for the farmer, because he has on his farm in most instances a few mares that are admirably suited for breeding purposes. They are both active and quiet and tractable in working, and will in most instances command a good price if sent in to the market. After selecting the mares, the next matter is to choose the sire. The wisest course is to take only the best that is offering, second-raters should not be tolerated. The paying of a little more in service

fees for a good animal will be found the cheapest in the end, as a better foal will more than compensate the initial outlay. Bad-tempered animals should not be used either as brood mares or as sires, as there is always the probability that defects in either animal will be transmitted to their progeny. Mares are all the better for being worked while in foal, as if not worked they are liable to get too fat, and then there is the danger of trouble at foaling. The foals should always be handled as soon as possible and kept quiet, as they never forget it, and are not so much trouble at breaking time. They should be left with their mothers until six months old, and when taken away should be kept well fed on chaff and bran and any green fodder that can be had at the time, and not turned out until the grass is sufficiently strong for them to do well on it. If fed properly they will not be stunted. When breaking time comes they should be carefully handled and mouthed; be firm but never bully. Firmness and quietness will do far more good than the whip and noise. When thoroughly handled the colt should be put to light work along with other good movers, with a view to teaching him paces. Never put him in a heavy load at first, as he may get stuck, which will probably teach him to jib. Sometimes jibbing is inherent, but in most cases it is learnt by the foal when being broken in." Mr. Noll pointed out that there were two types of Clydesdale—the "Shire" type and the "Modern" type. He thought the latter more suitable for the ordinary farm work. Mr. Slee thought horse-breeding did not receive the attention that it should. Breeders should choose the best and soundest sires and mares. He would rest mares when being served, although there were always exceptions to this contention. Mr. Farrell agreed that for farm work probably a little blood in draughts was desirable. He pointed out that mares should be worked to within four weeks of foaling, and also worked during the time of being served, but not when in season or during the day of service.

Wirrabara, November 23.

(Average annual rainfall, 30in.)

PRESENT.—Messrs. P. Lawson (chair), S. Thistleton, A. E. Stott, C. F. H. Borgas, W. H. Stevens, J. F. and E. Pitman, C. H. Curnow, W. Bowman, G. Hollett, H. E. Woodlands, and A. R. Woodlands (Hon. Sec.).

DESTROYING RABBITS.—Mr. Stevens reported that the system of tarring rabbit burrows had worked successfully where the ground was solid, but Mr. Pitman had not met with any success with the scheme. Mr. P. Lawson said bisulphide of carbon placed on pieces of bag and thrust well into the burrows, which were then made airtight, was most effective. Mr. H. E. Woodlands mentioned that carbide of calcium was equally good and much cheaper.

RUSTY NUTS.—These could be loosened by applying eucalyptus instead of kerosine. A very effective procedure was to bind a kerosine-saturated rag around the nuts and apply a light to it. With the assistance of the heat little difficulty should be experienced in removing the nuts.

MIDDLE-NORTH DISTRICT.

(PETERSBURG TO FARRELL'S FLAT.)

Crystal Brook, September 28.

(Average annual rainfall, 15in.)

PRESENT.—Messrs. M. P. Pavy (chair), W. J. Venning, R. R. Shaw, J. Pridham, B. Flavel, G. A. Solomon, J. Teakle, R. Heaslip, J. Duffield, A. Macdonald, W. Hutchinson, B. Weston, W. Carmichael, W. W. Lovelock, H. Sutcliffe, W. Jasper, H. Billingham, G. Miell, A. Story, V. Sargent, A. E. S. Clarke, W. W. Robinson (Hon. Sec.).

STRAW.—This subject was dealt with in the following paper by Mr. B. Weston:—"A little more than five years ago I built a stack of straw 9yds. long by 10yds. wide, finishing it off with a nice round top. During the winter months of two years the cows went to the stack every night for their bed. Whichever way the wind or rain was coming, the stock could always get good shelter, and this is undoubtedly a great benefit to cows

in milk. I used all Gluyas straw; I wanted it for shelter, and it answered the purpose splendidly. Although the stock have eaten a large part of it, the stack is standing to-day, except that the top was blown off about a month ago. I have since built two stacks of Marshall straw, and the stock have eaten both of them. I have also built another of Gluyas for shelter. I would recommend any farmer who has good straw to put together a stack as soon as possible after harvest. A few months back young horses and cattle would readily eat any clean straw that they could get, and no doubt the time will come again. Let us be prepared for it." Mr. Shaw, in discussing the matter, said straw properly stacked was of great assistance in tiding stock over dry periods, and also as shelter. Mr. Miell advised building a straw stack every year, and Mr. Teakle also thought this made good fodder for stock. A few years ago he mowed a good sized stack and mixed one sheaf of straw to three or four sheaves of hay, but he would not advise putting too much straw with the hay, as there was a possibility of harmful results. Last year Mr. Clarke had stacked a large amount of straw, mixing salt with each layer. His cattle had done remarkably well on it, but nevertheless he did not think it advisable to combine stock-raising with the growing of wheat to any considerable extent, as the stock cleared off the grass, &c., which should be utilised in the soil.

Georgetown, October 26.

(Average annual rainfall, 18in.)

PRESENT.—Messrs. W. J. Freebairn (chair), M. J. McAuley, A. Erichsen, W. Hill, Geo. Hill, E. Hewitt, J. Fogarty, A. Thomson, P. Higgins, A. Freeman, J. Myatt, S. Eyro (Hon. Sec.), and one visitor.

FARM BY-PRODUCTS.—Mr. J. Myatt dealt with this subject in the following paper:—"Every farmer should keep a few sheep. If he has a small holding it is not advisable for him to rear lambs, but to have some reserve feed, and purchase good young store wethers, about three years of age, off the shears, or in February. I prefer real good Merinos, as with crossbreds there is a difficulty in keeping them in the paddocks. If you have a fairly large holding in a suitable locality mate 100 large-framed full-mouth Merino ewes with two Shropshire or Dorset rams, and when the lambs are five months old they should realise 12s. per head; this, with an 80 per cent. lambing, is equal to a return of £48. You could also breed another 200 lambs for stock. They should be pure Merinos by the best rams that are procurable. Cows are another good addition to the farm. Three good cows kept and fed well should average £10 worth of cream per cow per annum without any very special feeding. They should have a liberal allowance of hay when the feed is scarce, and a bran mash occasionally with a few packets of Epsom salts—this would obviate trouble with dry bible. Each cow should be tested separately, and if she is not strong in butter fat dispose of her. I prefer the Shorthorn cow of the milking strain crossed with the Jersey bull. A few pigs can be reared on the farm and sold when they are about eight weeks old. If you have plenty of feed keep them until they weigh about 80lbs. and sell as porkers, not forgetting to keep a few to cure for your own bacon, for which purpose they should weigh about 120lbs. Poultry is an industry that is sadly neglected on the farm. First-class young table roosters will always bring a good price. I have reared cockrels which, at five and a half months old, weighed 7½lbs. (live weight). These would realise 7s. 6d. per pair at present. Mate Wyandotte, Orpington, Langshan, or Plymouth Rock hens with Indian Game, Modern Game, and Old English Game cocks. Do not keep any hens for more than three years. Turkeys are very profitable in picked localities, and good birds will realise from 10s. to 12s. each, and they require very little attention. Every farmer should have a small vegetable garden and grow his own vegetables during winter and spring. A nice flower garden and shrubbery will provide an attraction on any farm."

CAPE BARLEY.—Mr. J. McAuley reported having ploughed and sown with 80lbs. of super. and about 6bush. of Cape Barley an area of four and a half acres. This crop carried five cows, five calves, and four mares and foals for three months. This stock was removed from the paddock about a month ago, and he expected to reap about 20bush. of barley or three-quarters of a ton of hay per acre.

Leighton, October 24.

PRESENT.—Messrs. A. McDonald (chair), J. McDonald, I. J. Warnes, D. Williams, E. Jettner, R. McWaters, J. Earle, W. Morgan, R. Fairchild, T. Goodridge, A. E. McWaters (Hon. Sec.), and four visitors.

WORMS IN HORSES.—Mr. Goodridge read a paper on this subject, in which he reported the loss of a two-year-old filly, the death of which was indirectly due to worms. On making a *post mortem* examination he found the heart clogged with a mass of slimy matter, containing little air cells. He attributed this accumulation to the worms eating their way into the small blood vessels, passing to the heart, where they formed a mass large enough to choke the main artery. The provision of rock salt always available was a good preventive measure. Unlike the larger varieties the thread worms did not affect the condition of the horse to any extent. These parasites fed on the lining of the stomach, and while they did not deprive the horse of its food they destroyed a certain amount of the secretion which was necessary for the proper performance of the digestive function. Careful attention to feeding, stabling, and grooming horses would do a great deal in the direction of keeping the animals free of these pests. Mangers should be scalded occasionally: this would destroy any parasites lodged there. Members were of opinion that if more well water and less dam water were given to horses there would be less trouble with worms.

Mount Bryan, October 28.

(Average annual rainfall, 15½ in.)

PRESENT.—Messes. J. Tralaggan (chair). Wardle, Schmidt, Thomas, Stewart, Price, Nutt, and H. L. Hatherly (Hon. Sec.).

FALLOWING.—Mr. Thomas contributed the following paper:—"In a district such as our own there cannot be any fixity as to the correct way to work fallow, for not only do the soils differ to a great extent, but the circumstances also are very varied. One season we are blessed with early rains to start all weeds, thus enabling us to kill them by cultivating, whilst the next year we have totally different conditions. So a set formula is not workable. Each season presents totally different problems, which have to be met in totally different ways. All will agree that for convenience and effective working land must first be freed from all obstructions, such as stubble, &c. The ploughing should be done to a depth of, say, 4 in. to 5 in.; 4 in. being a suitable depth for new land, whilst 5 in. meets the case in stubble or old land. Ploughing should commence the first week in June, and be continued as expeditiously as possible until the middle of August at the latest—for two acres ploughed early and worked during the spring are worth three ploughed late and worked indifferently. Land ploughed early has every opportunity of absorbing all the winter rains, and also of consolidating again; which, in dry seasons, is a very important feature. To illustrate my meaning take the case of land that has been broken up dry, and consequently is lumpy. It will be found at seeding time, however you may work the top, it will have recesses or cavities below the seed bed, which are known to have a detrimental effect on the wheat plant. Land that has been ploughed early will be entirely different, for it will become firm. Certainly there are arguments against early ploughing, especially in close clay soil, but even this class of soil, if ploughed rough and not broken down too early, may be worked in this way. Sandy or loamy soil should not be broken down before the middle of August, for it is very liable, in the season of continuous rain, to become flat and set too close. Harrowing is usually more neglected than overdone, and I believe it pays to give it more attention. New ground especially should be harrowed twice with heavy harrows. The result will then be better work by the cultivator. Cultivating must be pushed on with where the soil is at all inclined to consolidate and become crusty, or it will be found a horse-killing operation to work the land to any depth. It might be well worth a farmer cultivating his fallow twice during the spring. In a district where the rainfall is sometimes light, such as we have here, the conservation of moisture in the soil is a very important feature. Certainly the experience of the past few years has not very strongly exemplified this, but nevertheless it is an important lesson which we may learn in the future. If we wait until after the heavy rains are over, and the ground is beginning to dry, so that we can by once cultivating kill all weeds, especially where there is stinkwort, we lose the opportunity of conserving moisture. During the last few days I have examined the soil which was cultivated early, and I found it damp to within ¾ in. of the surface; so damp in fact that weeds are still coming up on it. On the fallow which was only harrowed, and is being cultivated now, the moisture has nearly gone, leaving the soil crusty and solid to work. The question is, will it pay to do the double cultivating? Personally, I believe it will, but I should also like to hear the opinion of the other members on the subject. The farmer of the future must not only have a fair mechanical, but also a smattering of scientific, knowledge, for the time is fast advancing when soil will require a more unique method of manuring. At present we have many different classes of soils on the farm, but we usually use only

one kind of manure. This is certainly a mistake, but with the farmer's lack of scientific knowledge he is not able to decide for himself how to do otherwise. As time goes on it will become expedient for him to see into all these details."

North Booborowie, October 23.

PRESENT.—Messrs. Ashby (chair), Dunston, Birks, W. Tall, Morgan, W. Giles, K. and F. L. Phillips, W. C. and F. C. Catt, Smart, Mayfield, Roberts, Murphy, Storr, Sullivan, Barbour, Simpson (Hon. Sec.), and five visitors.

HAY-MAKING.—Mr. E. J. Dunston read a paper as follows:—"It is a wise plan to cut sufficient hay each season to allow for having some on hand at the succeeding hay-making. If stock are to be fed on hay I would advise cutting it fairly green, about a week after the bloom has come out on the head. It is then very sappy, and horses will eat it very readily. If the hay is to be chaffed I would cut it at a riper stage, when the grain has fairly well formed in the head. It is profitable to use chaff in preference to hay, as there is not the waste about it. If stock are fed constantly on chaff they prefer a change to hay for night feeding. If the hay is to be carted early after cutting I would allow it to lie a day before stooking, then put it into stooks of about 20 sheaves each. With ordinary summer weather it should be ready for stacking in 10 days or a fortnight; when the straw is brittle and will break at the joints it may be safely stacked. If stacked before sufficiently dry it is liable to sweat and discolor. The varieties of wheat I would advise for hay are those which grow a clean, bright straw, with plenty of flag, viz., Bluey, White Tuscan, Lott's No. 2, and King's Early. If the hay is to be chaffed I would mix oaten hay in the stack with wheaten hay, but would not feed oaten hay long, as stock eat the heads and leave the straw more than is the case with wheaten hay. It is profitable to chaff for winter feeding, as stock waste a great deal of hay when it is damp and tough. Where stubble land is cropped it is advisable to cut hay from that in preference to crops on fallow land, which frequently grow very rank. Build the stack north and south, as the sun then dries each side alike should it get wet before being thatched. Thatching should be well done with clean straw as soon as it is available after harvesting." Mr. Mayfield preferred hay cut just prior to flowering when it was to be fed to cows, but for horses doing hard work it was advisable to have it a little on the ripe side. A good fodder resulted from a mixture of White Tuscan wheat and oats. Mr. W. Giles was convinced that horses did better on oaten than on wheaten hay. Mr. Roberts thought oats should be fed for strengthening whilst wheaten hay was best for fattening. Hay for chaffing should be cut ripe, but that intended for feeding long should be cut on the green side. Mr. Murphy preferred solid straw, but Mr. Dunston considered that while the solid straw weighed well, it was not so good for stock. Mice generally did more damage in a stack when oats were in it. It was more payable to reap oats to crush and feed with wheaten chaff than to cut oaten hay.

Port Pirie, October 5.

(Average annual rainfall, 12½ in.)

PRESENT.—Messrs. E. B. Welch (chair), T. Johns, W. Munday, F. A. Johns, D. L. McEwin, H. G. Hawkins, T. B. Jose, H. and A. M. Lawrie, E. J. Eagle, and W. R. Wright (Hon. Sec.).

CLEANING AND MARKETING WHEAT.—Mr. Munday read a paper as follows:—"In the interests of those engaged in the wheat-producing industry, to my mind, to secure full value for the time, money, and labor spent in its production, it is necessary that more attention be paid to the cleaning and grading of same preparatory to placing it upon the markets of the world. It is somewhat of an anomaly to find that whereas in almost every other industry no time, money, or labor are deemed too great for the preparation of the various products in the most attractive manner possible, the wheat producer, with few exceptions, detracts from the value of his efforts by neglecting to pay attention to the proper cleaning and grading before marketing. While, it is true, there are a few amongst the producers of grain who take a delight and pride in thoroughly cleaning and preparing the grain, yet, I fear, there are many who are somewhat remiss in this respect, and who consider that, providing the sample, as taken direct from the harvest r, is up to the standard fixed by the Chamber of Commerce, the time spent in putting the grain through the winnower is so much time and labor lost. I am convinced that the enhanced value of the grain, if thoroughly cleaned, would more than compensate for the extra expense incurred in so doing. It is true, providing the crop be a fairly clean and

heavy one, and due care be exercised by the man engaged in manipulating the harvester, a fairly clean sample will result, but the amount of refuse in the cleanest grain, direct from the harvester, when shot and put through the winnower will be surprising. There is another, and, to my mind, important aspect involved in the preparation of wheat before marketing, namely, freight. It must be borne in mind that the broken and inferior grain and rubbish have to be paid for at the same rate of freight per ton as grain of superior quality and cleanliness, and while tending to injure the reputation of our grain in home markets goes eventually to feed the stock and enrich the fields of foreign countries, and by so doing enhances the cost to the local producer of the milling offal, such as bran pollard, &c. By thoroughly cleaning the grain the broken and inferior rubbish, if extracted, could be more profitably used upon the farm. I know there are a great number of farmers who will argue that it does not pay to spend more time and labor than is necessary just to secure an average f.a.q. sample, seeing that the wheat trader bases his prices upon those ruling in the world's markets, and upon the standard sample as fixed by the Chamber of Commerce. But I would point out that both grower and trader are partly to blame for this state of things; the grower, by neglecting to thoroughly clean and prepare the grain samples before submitting them to the Chamber of Commerce for standard purposes, and, secondly, the trader for not encouraging better methods of cleaning and preparing the grain before offering same for sale, by failing to give more per bushel for grain of superior quality and cleanliness. It is just here, to my mind, that much of the fault of placing upon the market wheat containing far too much rubbish lies. Probably from the trader's standpoint it is a matter of indifference, so long as he can dispose of the grain at a profit, whether it be properly cleaned and graded or not, and he may argue that the grower has no right to complain if he is paid the same for his inferior stuff, provided it complies with standard requirements. While this may be true to some extent. I hold that while we find in every other industry that it is quality that pays best in the end, it is only feasible to suppose that the same principle will apply to the wheat industry. Were nothing but clean and sound grain placed upon the market it follows that it must command a better price. Both traders and producers should co-operate in an endeavor to place upon the market wheat thoroughly cleaned and of finest quality, and thus enhance the value and reputation of Australian wheat in home markets. Then, again, there is another aspect of the wheat industry and marketing of same, which, to my mind, is far from satisfactory, namely, the storing of wheat with the trader prior to sale. While it may be an advantage to the grower to get his product away at the earliest moment instead of storing it in his shed or barn upon the farm, yet it must be borne in mind that the grower has to pay all the cost in connection with the housing and storing of same with the wheat merchant, and he can rest assured these items are calculated by the trader in basing his prices for the grain when purchased. I think this custom of storing with the trader shows a very confiding disposition on the grower's part, and speaks volumes for his faith in the honesty and business integrity of the trading fraternity. Without questioning for a moment these admirable qualities of our wheat traders I feel assured it would be greatly to the interest of the wheat producers to devote some of their cash to the purchase of sites, and the erection of sheds and stores at the outports and other centres for the reception and storing of the grain. They would thus retain full control until it was disposed of. With a view to inducing competition amongst wheat buyers they could offer and sell same by public auction in lots sufficiently large to ensure sales at a satisfactory figure. This would also minimise and tend to reduce the cost of running so many agencies, and retain for the producer the profits which now go to swell the banking account of the trader."

Redhill, October 29.

(Average annual rainfall, 16½ in.)

PRESENT.—Messrs. W. Stone (chair), McAvaney, Coffee, J. J. Hayes, E. Steele, Briggs, Pengilly, W. J. Burton, Robertson, Jackson, F., P. H., and F. A. Wheaton (Hon. Sec.), and three visitors.

HARVESTING.—The following paper was contributed by Messrs. F. and F. A. Wheaton:—"We foresee a change coming in the near future, for this district at all events, in the system of harvesting. The defects in the modern complete harvester are that every machine loses a certain amount of wheat, however good it is or however competent the driver. If a rain falls soon after a crop is harvested, shoots of wheat will be seen, no matter what machine has been used. Professor Lowrie, speaking at Crystal Brook last March, said he could not understand why farmers continued using harvesters when lighter and more effective implements were available; and when an authority

such as Professor Lowrie voices his opinion in such a manner there must be something in it. A harvester will not take a large foreign plant—*e.g.*, a turnip—through the comb or damp weather arrangement, and the driver has to stop and pull out the choke, thus wasting a certain amount of time. Perhaps the greatest defect lies in the fact that the seeds of wild plants, such as turnip, mustard, &c., are re-distributed, much to the detriment of the succeeding crop. If wheat lodges as a result of bad weather, or other causes, it is impossible to get all of it with the harvester. It is impossible to reap during damp weather; some grains are left unthreshed on the stalk, and part of the head is not threshed at all, but thrown out over the machine. This defect represents a serious disadvantage and loss to the farmer in a bad stripping season. Another point which, however, does not directly affect the farmer, is the uneven sample of wheat which is sometimes sent in to market. It is impossible to get an even sample, and at the same time always rely on getting the maximum result, for, if the crop is left till all is perfectly ripe, there is a chance of a large amount of grain being shaken out by a strong wind. Therefore it is obviously most economical to reap as soon as possible, *i.e.*, as soon as the machine will thresh the heads; but it is noticed that some parts of the crop are not quite ripe, and so the grain goes into the bags in a more or less unripe condition, much to the detriment of the sample. This must have a prejudicial effect on the sample of wheat that a country produces. It is readily understood, however, by all farmers that the great advantage of the use of the harvester is that it is a labor-saver, and this fact alone has, up to the present time, outweighed all its defects. Most of these remarks will apply to the ordinary stripper, but the advantage presents itself that you get a more even, marketable sample, as any green grain will ripen in the heap, but there is more time wasted in emptying the machine. With regard to the reaper-thresher, several advantages present themselves, and the first is that you are not troubled with chokes, as the wheat heads and anything else are cut off with a knife; and, secondly, it is easier to get wheat that has gone down with the reaper-thresher than with the harvester. This machine has not such a heavy draught, and takes a wider cut than the harvester. A great disadvantage with the reaper-thresher is the big strain on the horses and the machinery when starting. To overcome this difficulty it might be possible to incorporate an engine with the reaper-thresher to drive both the stripping and threshing machinery, and to propel the machine itself by separate gears. This would enable the stripping machinery to be set in motion at full speed before the machine entered the crop. We are of opinion that this method of using reaper-threshers would be preferable to hooking machines on to a tractor. The system of harvesting which we judge to be superior to any mentioned above is binding and threshing, and as the paper proceeds we hope to give you some logical reason for our recommendation. The thresher is portable, and can therefore be set down in the paddock where the crop is. The wheat is carted to the thresher direct from the stock. The straw, when leaving the thresher, is stacked as required, or is pressed, and cocky chaff is thrown into a heap. The machine can be driven by the farm tractor, which will be coming into general use. The advantages associated with this system of harvesting are as follows:—(1) You are able to start harvesting 10 or 12 days earlier than you can with harvester. The crop can be cut as soon as the doughy stage is reached; the grain ripens evenly and you get an even sample of seed. (2) The straw which you obtain from the thresher is more palatable to stock than stripped straw, and is also of better feeding value, as it is so much greener. Straw can be stacked till needed, and in a year like the present a few stacks of good straw would come in very handy. (3) The trouble that is experienced in the matter of chokes when stripping is overcome by the use of the binder. It is a much more easy matter to clean land of weeds, and in a district such as ours, where mustard and turnip thrive so magnificently, this is a great advantage. (4) The stubble land is so much easier to plough, and the straw does not need to be burnt off. (5) Perhaps the greatest advantage lies in the fact that you can cut the crop before it has a chance to lodge or shake out. Even if the crop does lodge it is a comparatively easy matter to get it with the binder. We have known half of a 30-bush. crop to shake out during a strong wind within a couple of days of the wheat being fit to strip. (6) No grain is lost during the harvesting operations. (7) You are able to work in cool and damp weather. In some countries where this system of harvesting is in force the crop is cut and stacked under cover and threshed when convenient; but this is only when the summer season is a very short one. Our special point in this connection is, however, in the fact that the land is kept clean. Mustard and turnip are, as you all know, completely spoiling some crops, and this is the only system of harvesting which we can at present recommend as being able to cope effectively with the crop and at the same time keep the land clean. A very good thresher can be purchased for less than £200. Many of the present day threshers cost £100. A good

harvester costs a little less than £100. It is safe to say that a thresher will last twice as long as a harvester. We consider that three binders will go over as much ground as two harvesters, and that a binder and harvester will each last 10 years. It will be understood that the length of use of binders is calculated for cutting wheat or other grain crops. Of course, if the machines are used for cutting hay they will not last so long. Admitting that a thresher will last 20 years, a harvester 10 years, and binder 10 years, the figures work out as follows:—

Three binders, £130 1st 10 years	Two harvesters, £200 . . 1st 10 years
Three " 130 2nd 10 "	Two " 200 . . 2nd 10 "
One thresher 200 20 years	
Total . . . £460	Total . . . £400

That means £60 less cost when harvesters are used; but we think that the extra sum required would be amply repaid by advantages gained, viz., not so much grain lost during harvesting operations; the acquisition of a better name for your grain and hay through not having any mustard seed; and other advantages which have been mentioned during the course of the paper. The great disadvantage however, that lies in the use of the thresher is the cost of labor; but, to get over this difficulty, we suggest co-operation among, say, three farmers or more, as the necessity arises. If this were carried out the difficulty would be overcome." In discussing the subject, Mr. Coffey expressed the view that the cost of labor would render impracticable the system recommended in the paper. Co-operation would not be a successful means of overcoming that difficulty in the majority of cases. Messrs. Burton and Steele agreed that there would be too much waste of grain on a hot day in the process of carting, but Mr. Briggs thought that if this occurred it would be due to the fact that the wheat had not been cut early enough. Mr. McAvaney agreed with the paper in the matter of cleaning the land, but thought we would go back to strippers and winnowers in a few years, as a better export sample was procured when these were used. Mr. Stone did not think we would go back to strippers. Harvesters had come to stay in clean districts. For other districts, where turnip, &c., had a good hold, he thought that part of the crop would be harvested and part gathered with the binder and thresher. Other members preferred the complete harvester, some the stripper and winnower, but most of them considered that the threshing would be too expensive.

Spalding, November 15.

PRESENT.—Messrs. E. E. Gill (chair), Work, A. B. Jones, J. H. Pluckrose, T. Walsh, G. Thorn, D. Shane, P. A. Gill, D. A. Campbell (Hon. Sec.).

HOMESTEAD MEETING.—The meeting was held at the homestead of Mr. E. Gill, who supplied the following notes for the guidance of members:—"In a district like this, that is totally devoid of natural timber, plantations of useful and ornamental trees are very important. I find the trees that do best are sugar gum, red gum, *pinus insignis*, *pinus maritimus*, pepper, white acacia, white cedar, poplar, and cypress. The ground should be ploughed to a depth of 6in. or 7in., and the planting done early in winter, to get the trees well established before the dry weather sets in. The pines must be securely staked and the gums and peppers protected, with half a super. bag kept out with four sticks, against the frost and strong winds. The bags should be left around the trees until November. If the spring or early summer is dry it is advisable to water the trees, and the ground around each must be loosened up after each heavy rain or watering. This seems a lot of work and trouble, but it will result in 100 per cent. of the trees living. As each tree well established is worth a sovereign, you are well repaid for the work. There are no vacant spaces in my plantations, and the growth of the trees, i.e., 6ft. in one year, 12ft. to 20ft. in three years, and 34ft. in five years, shows that if my system is not the correct one it is one that is fairly good. The hedges around the homestead are useful as break-winds, and some of them are very ornamental. There are six different hedges, planted two years and four months ago, consisting of, in the order of their growth and suitability to the district, African boxthorn, tagosaste, tamarisk (deciduous), *Cupressus Lambertiana horizontalis*, *pittosporum undulatum*, and Kia apple. There are also *rhamnus*, *coprosma lucida*, *lauristinas*, *nerium*, and *bougainvilleas*. These are good hedges, but cannot be compared with the others, as they have only been planted 16 months. Climbers around the house which are doing well are *kennedia nigricans*, *bougainvillea*, and *tacsonia*, which are evergreen, and *wisteria*, *Ampolepsis engelmanni*, and *Ipomoea Leari*, which are deciduous. It is advisable to plant deciduous climbers near windows so that the foliage will not interfere with the light in the rooms in the winter time. Climbing roses, which make a fine show

and protect each other from the wind and sun, are Dorothy Perkins, Niphetos, Fortuniana, crimson rambler, Banksia, climbing Maman Cochet, Liberty, and Caroline Testout, and McCartney grandiflora. The last named is a magnificent climbing rose. Every homestead should have a patch of green fodder through the summer. This helps the cows and poultry, besides being a beauty spot. I find lucerne far the best and maize next. I have also *Paspalum dilatatum* and veldt grass, but you can see that these are not to be compared with lucerne and maize. The average farmer will tell you that his well water or creek is too salt for a garden, when very likely, if he would try it, he would find that it is all right for irrigation purposes. The water I use, pumped from a running creek, was analysed by the Agricultural Department in February (when the creek was normal) and showed the following analysis, dated February 10th, 1906:—

Total solids in grains per gallon	183.00
Chlorine	88.2
Equivalent amount of common salt in grains per gall. .	145.5
Calcium in grains per gallon	7.5
Magnesium in grains per gallon	10.35
Carbonic acid (CO ₂).....	9.00
Temporary hardness	15°
Permanent hardness	44°
Calcium carbonate	15.00
Magnesium carbonate	nil
Sodium carbonate	nil
Magnesium, sulphate, and chloride	40.2

The officers of the department at that time were of the opinion that the large quantities of magnesium and alkaline salts made it an inferior water, except perhaps for lucerne or plants of a similar hardy nature as regards salt. In fact, one officer told me that it was a water that should be used with caution, unless I pickled meat with it, then I would find it nearly right. The results would be watched with interest as he thought the information derived would be of value to the department. I pump the water with a 3in. centrifugal pump, and the power used is a 10-h.p. Blackstone oil engine. This plant has been running for six years, and millions of gallons of this water have been run over trees, lucerne, maize, sorghum, mangolds, tomatoes, the vegetable garden, and the flower garden, and up to now no signs of deterioration have appeared on any part of the land treated, and enormous crops are still grown. The land is dark loam over a limestone subsoil, the subsoil being from 8in. to 2ft. from the surface; none of it is subject to flooding from rain, except the flower garden, which is flooded after every heavy precipitation. [Mr. Gill has now been asked by the Department of Agriculture to supply a further sample of the water, so that the quantity of alkaline salts may be determined to see whether there is still such a high percentage present as was the case in 1906.—ED.] The engine also supplies the power for the chaffcutter, circular saw, corncrusher, and grindstone; these are all necessary on any well-appointed farm, and with a galvanized iron shed, all can be used in wet weather when it is impossible to work horses on the land. The cost of kerosine and upkeep for the engine is very small. I would also like to point out the usefulness of a good incubator, as it enables a farmer to keep up his supply of young birds, with very little trouble and expense. You will notice a clutch of 132 chickens and 47 ducklings, three weeks old, strong and healthy. They were hatched together in a 200 egg Simplex incubator—a brooder was not used—the ducks having a week's start. I have worked this machine for nine years and it has hatched out thousands of chicks and ducks for my neighbors and myself. The machine stands in a galvanized iron house 8ft. by 10ft. The reason for hatching so late in the season is that the chicks require no artificial heat. The provision of a rainwater supply is also very important. I prefer galvanized iron tanks to underground tanks, as being above ground they do not catch so much dirt and debris, and as all the supply is not in one tank, some of them can be cleaned out at any time. A 2-in. plug soldered into the bottom of each tank facilitates cleaning. A small space must be left in the stand or foundation in which to work the spanner to screw the plug out. I use 2,000-gall. and 3,000-gall. tanks, and where they are situated away from the house I have them connected with 1½in. piping, with a rubber connection between the tank and the piping to overcome expansion troubles in hot weather."

Whyte-Yarcowie, October 19.

(Average annual rainfall, 13½in.)

PRESENT.—Messrs. G. F. Jenkins (chair), G. D. and J. R. Mudge, Robinson, J. E. and F. Hunt, McLeod, Lock, A. Mitchell, E. J. and F. Pearce (Hon. Sec.).

HAY.—Mr. E. J. Pearce read the following paper on this subject:—"In this district it has not been the custom to cut much more than enough hay to supply the farm. It will, however, no doubt be found profitable to do more in this line in the future. Last season, for instance, an untimely frost cut and spoiled some crops which, had they been made into hay, would have returned their owners a value equal to that obtained for a similar crop unaffected by frost. In seasons when we have a good growth of straw, it is always wise to cut much more than enough for the current year's requirements. Doubtless the supply in the district will lead to better facilities than exist at present being provided for marketing. The question as to which is the best variety of wheat to grow for hay purposes in this district is one that will be answered differently by different persons. For the past three years I have been experimenting with Le Huguenot, and I have found it a success, as far as length and weight of cut are concerned. It seems to be more hardy than most kinds. It certainly is a heavy weighing variety, and the stock eat it well. Its faults are: It is a difficult matter to get it to grow thick enough on any but the best of soil, it is a bad crop to harvest for seed (and of course it is not suitable for milling), and there is a doubt as to its feeding value, that is, weight for weight in comparison with other varieties. Mr. McEwin, of Jamestown, said his horses failed to do well on it at Pinnaroo. They scoured and fell away. A Belalie farmer, Mr. Jno. Coles, said it was a fine hay wheat; horses liked it and did well on it, the trouble was to get it thick enough. Two or three years ago Mr. Colebatch said they had used it at Roseworthy and had not noticed any ill effects from its use at the College, and a chemical analysis showed it to be richer in food qualities than ordinary wheats. I would not recommend any one to grow this variety in large quantities, but it is worth while to sow a fair portion of the hay land with it. Another good variety grown in this district, and of extra value, on account of its being also a good variety for grain, is Dart's Imperial. A variety not so well known, and perhaps unsuitable for a good part of the district is Bobs. Both these grow a long straw of good color. Le Huguenot should be cut whilst green, as soon as the grain is well formed. With the other varieties I like, for feeding purposes, to have a fair amount of corn in the head. Stock relish it more and less of it satisfies them, but there is the objection that the mice cause trouble. In most districts, since the advent of phosphates the crops very rapidly pass the most favorable stage for cutting, so it is advisable to begin cutting when the crop is on the green side, in order to get through before it is too ripe. In this way it will be found that the hay will average a good quality. I like to bind it in a good large sheaf, but one has to be guided to some extent by the crop and weather conditions. If the hay is very sappy or the weather moist and cool, there is danger of the sheaves not drying through sufficiently. Under these conditions a smaller sheaf is safer. If the ground and weather are dry and warm, it is scarcely possible to stook the hay too soon after the binder, but in doing so care should be taken not to make the stooks too large. I am not in favor of large stooks at any time, as, if we get a fall of rain, as often happens whilst the hay is on the field, it soaks through and fails to dry out quickly enough. I would not build the stooks more than four sheaves in width, two leaning against two, with an air space through the length of the stook. The sheaves should be so laid that when the stack settles down they should slope downwards from the centre to the sides. Then, if care is taken to keep the centre of the stack well filled, there is little danger of a rain of an inch or so doing any harm and making it necessary to throw off a part of the stack to dry. There is also far less likelihood of the stack sustaining damage from winter rains. Stacks should be built east and west. I believe it to be a paying proposition to erect a permanent roof of timber and iron. The waste sustained each year at the top and bottom of the stack would, in less than 10 years, pay for same." In discussing the question, Mr. Robinson said he favored stooking to a width of three sheaves, as the hay then dried much more quickly. Smart's Early was a good hay wheat, and he thought the idea of having an iron roof one well worth consideration. Mr. J. E. Hunt was also of opinion that it would pay to put iron roofs on stacks. He had found that horses did not take well to Le Huguenot wheat if it were fed long, but when chaffed they ate it readily. Mr. G. D. Mudge thought it a good idea to stack the hay on a layer of old posts. This kept the sheaves at the bottom from being damaged. Mr. Mitchell considered a good layer of straw was sufficient cover, especially if it were kept in place with wire netting. Mr. F. H. Lock thought that oats would not pay as a hay feed, but they were of great value when mixed with chaff and used as grain. King's Early was a good wheat, but Smart's Early was not nutritious. He preferred cutting the wheat for hay when the grain was fairly full. Mr. G. F. Jenkins thought Le Huguenot a very good hay wheat and his horses had done well on it. Dart's Imperial was a good hardy wheat. Sheaved barley straw was an excellent foundation on which to build the stack.

Yongala Vale, November 16.

(Average annual rainfall, 13½in.)

PRESENT.—Messrs. C. Fowles (chair), T. Battersby, W. Edson, J. and G. Lloyd, E. Fowles, B. Webb, W. Keatley, G. H. Jansen (Hon. Sec.).

HARVESTING.—Mr. E. Fowles read a short paper on this subject. The crop for hay, he said, should be cut as soon as the blossom had disappeared, and it should then be immediately put up in stooks consisting of no more than 15 to 17 sheaves. The best varieties of wheat for hay were, in his opinion, Dart's Imperial and Marshall's. He would not recommend growing oats alone, but mixed with wheat; this would provide a good hay crop. Stacking should be commenced immediately the sheaves were dry, and the stack should be provided with a cover as soon as good straw was available. It was not advisable to put the stacks too close together, nor should they be in proximity to an engine-shed. In building it was advisable to keep the centre well filled up, then if a thunderstorm were experienced little trouble would be encountered. The top should be commenced when the stack had reached a height of 18ft. Reaping should be commenced immediately the crop was ready, whether the hay had been put in or not. Bags should be sewn as soon as possible after reaping, and wherever practicable a tarpaulin could be used on which to stand the bags, and this would save a considerable amount of wheat. Where operations were started too early in the morning it would generally be found that the thresher was much more difficult to work, and in the long run this did not pay.

LOWER-NORTH DISTRICT.

(ADELAIDE TO FARRELL'S FLAT.)

Balaklava, October 12.

(Average annual rainfall, 15½in.)

PRESENT.—Messrs. H. P. Burden (chair), W. J. Gleeson, F. Wagner, R. S. Goldney, G. C. Neville, H. Roberts, J. Spillane, H. L. Twartz, P. Roediger, O. Uppill, B. R. Banyer (Hon. Sec.), and one visitor.

FALLOW.—Mr. Uppill read the following paper:—"Nearly every year we are confronted with some difficulty in working our fallow, with the result that a portion of it does not get the treatment we desire. At some period of the year, either when the spring working should be done, or at seeding time, it is, perhaps, too wet or too dry, consequently it gets in a very dirty condition with all kinds of weeds that are encouraged by the continual use of heavy dressings of superphosphate, and of which it is a very difficult matter to be rid. My experience is that by the ordinary treatment we give our land it is almost impossible to again get it clean from rubbish; in fact, with some kinds of land the working would cost as much as is received for the crop. The difficulty is to get the seeds to germinate. Every time the land is moved a fresh lot will start, and wild oats have been known to stay in the ground for 15 years without germinating. To meet the difficulty I would advise cropping every second year, or adopting a rotation of wheat, fallow, wheat, and so on for a few years, until the land proves to be clean enough for the usual rotation. Each year the stubble should be burned off at the end of the summer, a light implement, such as scarifier harrows in plain land, and a spring-tooth cultivator in rough land, run over the land before rain, and then the harrows applied, to make the top surface fine and dusty. This will give the weeds a chance to start at the most seasonable time of the year. If the weather and land are suitable, a cultivator can be used directly the seed is in and before ploughing. This will help a further germination before any seed is ploughed down. Then the usual course of cultivation after every rain must continue for the rest of the year. With the ordinary three years system of cropping the weed trouble is one of the greatest difficulties. Only particular kinds of land can be ploughed in the autumn, and the plough in any case is the only first means of cultivation, whether then or in the usual time, with the result that the weeds are turned down to the bottom of the ploughing, and the cultivator only brings them to the surface by degrees. How long this theory can be carried on remains to be seen, but I know of two instances where farms have been worked under similar conditions to these for at least six years,

and last season, although an unfavorable one, they produced 22bush. and 25bush. averages respectively. Where a farmer goes in for keeping stock he will certainly feel the loss of a stubble paddock for early feed. A coat of super. could be put over the grass paddocks in the autumn, which would ensure a crop of good quality grass." Mr. Gleeson said the idea would work well enough in a suitable season, but in a season like the present the difficulty was to get the rubbish to grow. Some farmers in his district had gone in for summer working with the cultivator. Last year they had had good results. He thought there was nothing like fallowing early, and working it as the rubbish needed, keeping the fallow as fine as possible. The skim plough was more useful than the cultivator, as it gave a better bottom. He did not think it wise to work the fallow after every rain, especially in windy weather such as had been experienced lately, as there would be a tendency for the soil to drift. Mr. Roediger said the method of working land depended upon the class of soil. He did not think they could work the fallow too fine. He thought the harrows might be used after heavy rains. He had noticed that stubble paddocks fallowed down seem to stand the dry weather better than those standing for three years. Mr. Goldney said the difficulty was that the weeds did not all germinate at the same time. Charlock caused them trouble. He believed wild oats germinated after being in the ground for many years. Mr. Neville said the best crop on his farm was on land that had been burnt off and fallowed for the third time. If land were held over for a couple of years the weeds took all the superphosphate that was left in the ground from the crop. If burning off were adopted the weeds had not the same chance. Scarifier harrows were the best for the purpose of keeping the weeds from getting a good start. Mr. Roberts thought the more the fallow was worked the better. A neighbor of his had harrowed his crop, leaving a strip a chain wide. The difference was very marked. It seemed to prove that harrowing about a week after sowing helped to get rid of weeds. Mr. Spillane thought a good plan was to run the cultivator over the land in March, and then harrow just before sowing, which would get rid of a lot of rubbish. Some of his neighbors had tried continual cultivating, and it seemed to answer, but he did not think that killed the weeds, but worked them up. He thought the land should be worked lighter. Mr. Twartz said ploughing deeply had always been advocated, but his experience was that shallow ploughing was the better under his conditions.

Blyth, November 14.

(Average annual rainfall, 16·28in.)

PRESENT.—Messrs. A. L. McEwin (chair), J. S. McEwin, T. Dunstone, W. Pratt, J. J. Clarke, R. Buzacott, C. Lehmann, W. H. Best, F. T. Pedler, D. Crawford, J. B. and F. A. Kirchner, J. and T. Williams, J. T. Harmer, Dr. A. V. Heynemann, H. W. and W. O. Eime (Hon. Sec.), and two visitors.

HOMESTEAD MEETING.—The meeting was held at the homestead of Mr. A. L. McEwin. Members inspected the wheat crops. A paddock of 950 acres of Marshall's No. 3 looked very well. It was sown on good fallow with 70lbs. of seed and 1cwt. of super., 38 to 40% soluble phosphate. Penny wheat was not so well headed as the former crop. Sixty acres of Federation were sown on fallow that had not been ploughed; the stubble was cultivated in March and again twice between seeding time and harvest. No difference could be noticed between this and the ordinary fallow. Alongside, a small strip of King's Early looked inferior to the other crops. Silver King and Yandilla King looked best of all, and promised 30bush. per acre. These two varieties were sown on fallow about the middle of April. No rain fell until the end of May, and patches came up before the rain. Federation looked to be the only wheat that had suffered during the dry spell; it was also the thickest. All were sown with the same amount of seed and manure. The horses were next inspected, and they consisted of good draughts. Mr. McEwin owed his success to breeding from young stock and good feeding. The hay shed was admired by several. It held about 200 tons, and Mr. McEwin had just erected a large implement shed of iron, so arranged that he could shelter the sheep in it over night during shearing.

REGISTRATION OF STALLIONS.—In a paper dealing with the proposal embodied in the resolution passed at the last Congress of Agricultural Bureaux, recommending the Government to make provision for the compulsory registration and examination of all stallions travelling for hire, and limiting the number to travel in a district according to the requirements of the district, Mr. J. S. McEwin said—"This is nothing more or less than a tax on stallions, and no matter who pays it in the first place, in the end it is going to revert to those who require the services of the horse, and in nine cases out of ten they will be the men on the land. As the manufacturer has to pay more for his labor or

material he puts the price on the finished article, and such will be the case with the registration. The more expense the owner is put to the higher will he raise the fees. I am perfectly satisfied that the breed of horses in South Australia is improving, and a much better stamp of horse is to be seen on the farms to-day than would have been seen 10 years ago. With the man who has a team of mongrels the main fault is neglect. If they were properly cared for they would look better and do much more work, the more especially if they were properly looked after up till they were four years old. We have proved that horses that have never had a check up till that age are more easily kept after they are put to work, and develop much better. If farmers pay more attention to feeding their horses, and the breeding standard improves at the same pace during the next 10 years as it has in the past, the horses of South Australia will be very creditable. The present form of examination of stallions is sufficient. A man knows whether he is breeding from a sound horse or not, and if the horse has not a certificate of soundness the breeder must run the risk of his foals being sound or not. If only horses that travelled for hire were to be registered we would have more mongrel stallions than before, for this reason, the well-to-do farmer now will only use the best horse he can get, and as a rule the farmer who has just started, and is not so well off, cannot afford to use a high quality horse because his fees will be higher than those of a poorer type of horse. The result will be that he will keep a colt of his own, because he will do the work of an ordinary horse, and there would only be a little extra trouble in looking after him; consequently we would be no better off than before." Mr. Lehmann, who agreed with the remarks made in the paper, said he thought the inauguration of a stud book would tend toward an improvement in the quality of horses. Mr. Buzacott believed in the registration of stallions, even when they were only kept by the farmer for his own use. The Branch took a vote on the subject of registration and the introduction of a stud book, members expressing an opinion in favor of both.

Clare, October 25.

(Average annual rainfall, 24in.)

PRESENT.—Messrs. D. Menzie (chair), J. Berridge, P. R. Pascoe, F. Keane, F. Pryor, A. Hill, F. W. H. Lee, J. Dux, F. Pink, A. J. Lee, A. Pyecroft, M. L. Nolan, C. P. Jarman, F. W. Hicks, S. Pascoe, C. Scott, R. Stewart, R. Hunter, E. Kelly, W. Taylor, E. Victorsen, J. C. Radford, C. J. Radford, J. H. Knapppstein, H. A. Hanna, F. J. Gerteau, and P. H. Knapppstein (Hon. Sec.).

WHEAT FOR DISTRICT.—Members were generally agreed that the most suitable wheats for hay in this district were Marshall's No. 3, King's Early, and Smart's Pioneer. Federation and Silver King were the best kinds for grain.

FROST-BITTEN VINES.—It was thought advisable to rub off affected shoots of vines that had been frost-bitten, as this practice gave the base bud an opportunity to send out another strong shoot.

Friedrichswalde, October 19.

(Average annual rainfall, 19in.)

PRESENT.—Messrs. Goodfellow (chair), F. Heintze, R. Marlow, F. W. and E. Duldig, J. Michalane, Coombe (Hon. Sec.), and three visitors.

CULTIVATION OF FALLOW.—Mr. P. Goodfellow read a paper on this subject as follows:—"The cultivation of fallow is an important item to the up-to-date and successful farmer, but the remarks I make will not apply to all classes of soil and climate. For local conditions I plough immediately after seeding is finished, to a depth of 3in. or 4in., and every second or third cropping to a depth of 5in. As soon as the ploughing is completed the land should be logged. I prefer logging to harrowing, as the surface is made level, and more clods are broken. At the beginning of October the land should be worked with a heavy cultivator to the full depth of the ploughing, and the working should be continued until the whole area is gone over, whether the soil be wet or dry. By cultivating to the full depth of the ploughing the soil is kept open, thus permitting the absorption and retention of more moisture than would otherwise be the case. The influence of the sun in sweetening the soil will also be greater than if the soil is worked shallower. Should any summer weeds appear before harvest it pays handsomely to go over the fallow with a spring tooth cultivator, which implement is sufficiently heavy to destroy the weeds. As soon as the harvest is completed, the land should again be gone over with a ribbed roller, with the object of breaking the clods and levelling the surface. Before drilling is commenced it should be cultivated with a heavy cultivator to a depth of 2in. Each

working should cross the previous one. Fallow treated in this manner will amply repay the farmer for the labor and expense involved, as by the conservation of moisture, the sweetening of the soil by exposure to the sun, and the destruction of weeds, the succeeding crop will benefit immensely." The majority of members favored the harrows in preference to the log immediately after the first ploughing, as although the land was perhaps not made so level, it received an extra working which would be beneficial to the succeeding crop, and the soil would not set so hard in the event of heavy falls of rain. Otherwise members supported the writer of the paper in the various points brought forward.

HAY-MAKING.—A paper dealing with this subject was read by Mr. E. Duldig as follows:—"Hay-making is an important item to the farmer, as so much depends on the feeding of his horses. If he purposes cutting more than the requirements of his own stock it is advisable for him to start a little earlier than he otherwise would. For feeding hay should be cut as soon as the grain is properly formed, it will then contain sap as well as grain. If cutting a considerable amount it will be necessary to commence before the 'flower' leaves the wheat. For sale purposes, the hay should be cut still greener, to get as much sap as possible. This will give the chaff a nice green appearance, and it will sell more readily than hay cut later, although the latter will weigh better. Immediately after the hay is cut put it into stooks of about 20 sheaves each, placed upright, with the outer ones leaning to the centre. This forms a roof to the stook, and little damage will be done should rain fall. By making small stooks the hay can be carted sooner than if larger ones are made. Ten days should elapse before carting is commenced, as then the hay will not be too dry, nor will there be any risk of it going mouldy in the stack. The stack should be built east and west: heavy westerly storms will then only beat on one end of it. The foundation should be level all round the edge, with the centre at least 2ft. higher. This will give a slope to run off any water. It is advisable to build only one sheaf high all round the stack, and then there is little likelihood of it slipping. round ends are the best, and the dimensions should be in the proportion of at least 3yds. long to 1yd. wide. If the stack is to remain intact for any length of time it should be thatched and made mouse-proof by cutting sheets of iron lengthways and putting them 3in. in the ground close to the stack."

Friedrichswalde, November 16.

(Average annual rainfall, 19in.)

PRESENT.—Messrs. Goodfellow (chair), J. and F. Heintze, F. W. Schutz, F. W. Duldig, R. Marlow, A. G. Reichelt, G. Grope, and Coombe (Hon. Sec.), and seven visitors.

HARVESTER v. STRIPPER.—F. W. Duldig read a paper supporting the use of the complete harvester, as follows:—"In all professions and trades at the present time the most up-to-date machinery is being used, and it behoves the farmer to be in line. He must have a complete harvester, so that he can take off his own crop without encountering labor difficulties, and in less time than is required with an ordinary stripper and winnower. With a complete harvester weight of wheat is gained and wages saved. A contract might be let for sewing at the rate of 1d. per bag. This would be a good deal cheaper than gathering the crop with the stripper and paying 5d. or 6d. per bag to have it cleaned. With a harvester it is possible to start a little earlier in the morning, and also to work in cooler weather than with other reaping machinery. I have harvested over 100 acres with a harvester in the same time that it has taken my neighbor to strip 30 acres with a stripper, on account of cool weather. With a harvester there is a better chance of securing an early market for the wheat. It is not advisable to start stripping before the wheat is properly ripe, although I have done so and secured good returns. The cocky chaff can be saved by a carrier attached to the machine. Chaff saved in this manner is free from dirt and sand, which are the causes of more sickness in horses than is usually recognized. The farmer using the harvester should cut sufficient hay to see him through the year; but if there is likely to be a shortage a good idea is to cut some good wheaten straw and chaff this with the hay. The waste of wheat with a harvester is no greater than that with the stripper. Amongst other faults the harvester is credited with is its tendency to distribute seeds of weeds over the soil, but as a rule the seeds are on the land before the wheat is harvested, and by adopting a proper system of fallowing and cultivation the farmer should have very few weeds with which to contend." Mr. F. W. Schutz gave a paper to the following effect:—"It would be interesting to know the number of strippers and harvesters in use in the State. Both machines apparently have a lot to recommend them. Under certain conditions the harvester is perhaps the better machine, but this district does not provide the necessary conditions; in fact, very few districts in the State do. In the first place the hilly nature of the local land favors the use of the stripper, as, however capable the person in charge of the harvester may be, he will be unable to

prevent loss of grain and obtain an even sample. When the harvester is going uphill the fans, and in fact all the mechanism, are of necessity working slower than if the land were level, and this permits a good deal of rubbish to work through the sieves into the wheat box. When descending a hill the pace is increased in all parts of the machine, and wheat is consequently thrown over the tail with the chaff. When using a hand winnower for any purpose it is necessary to see that the machine is standing level, that the handles are turned regularly, and the machine is fed regularly. If it is necessary to do this with a stationary winnower it is surely equally so on the harvester-winnower. Then there is the saving of horseflesh, in itself an important item; but more important still is the saving of horse feed, in the shape of cocky chaff. The value of this cannot be overestimated, as mixed with pollard or bran and corn it makes a capital feed for stock, and can be made to take the place of hay chaff without any detrimental effects. The value of this feed will be realised when the price of hay rises. The harvester is certainly old when it has worked 10 seasons, although there are exceptional cases: but a stripper is in its prime after 30 seasons' work. Of course, a winnower has to be purchased, but after the first outlay the expense is so small that it need not be considered at all, and apparently winnowers never wear out. The stripper and winnower, costing about £75, last three times as long as the harvester, costing £85. Owing to the additional mechanism and complications on the harvester the breakages and delays are numerous, whereas the stripper will work year after year with absolutely no delays from this cause. Delays are sometimes very expensive, as two or three days are lost in obtaining new parts. One or two bad seasons will see the stripper more in evidence, while the harvester will be used to supply the rest of farm implements with bolts, nuts, &c." A lengthy and thorough discussion followed, and on a vote being taken a majority of one supported the harvester.

Greenock, October 26.

PRESENT.—Messrs. J. Jungfer, A. Nitschke, W. F. Nitschke, H. Koch, O. Semmler, E. Geyer, W. Roenfeldt, E. Roenfeldt, Aug. Heinze (chair), V. Koschade (Hon. Sec.)

FALLOW.—Mr. Aug. Heinze read the following paper:—"The method of farming practised now is vastly different from that of 25 or 30 years ago, and the farming community is greatly indebted to such men as Professor Lowrie, our present Director of Agriculture, and Mr. Molineux, who did so much in the direction of introducing scientific methods of farming, which have now become general. Fallowing was carried on by some of our practical men even 20 years ago, but the ploughing was always done late in the season and not started until winter was over, and the land was ploughed in a dry state, thus there was no moisture conserved in the soil. It is absolutely necessary that fallowing should be started as early as possible in autumn, in fact as soon as possible after seeding is completed, and be finished before the winter rains have ceased, in order to get as much water as possible down into the soil. The depth of ploughing naturally depends much on the nature of the soil, and in our district I consider 4in. to 5in. quite deep enough for the first ploughing. A plough cutting a 7in. furrow is certainly preferable to one cutting a 9in. furrow, and a five-furrow plough cutting a 7½in. furrow is drawn more easily by the same team of horses than a four-furrow cutting 9in. The 7½in. furrow implement will certainly give much better results. After the ploughing the land should be cross-harrowed to break the sod; this at the same time will cause weeds to germinate and grow all the quicker. After the cultivator has been over it the land should again be harrowed. If fallow is allowed to remain unworked and to harden, moisture is lost from the soil by capillary action and evaporation. If it is continually worked, only shallow working is advisable. I prefer ploughing to scarifying, because weeds, which in all probability will and should grow, are turned under and add humus to the soil."

Nantawarra, November 21.

(Average annual rainfall, 15in.)

PRESENT.—Messrs. R. P. Uphill (chair), S. Sleep, E. J. Herbert, A. F. Herbert, J. Nicholls, R. D. Nicholls, J. Sinclair, W. Smith, W. Greenshields, F. J. Sutton, and G. L. Tucker (Hon. Sec.).

SOCIAL LIFE ON THE FARM.—Mr. W. Smith read the following paper:—"Farm life should be full of the spirit of pleasure. Such an attitude toward one another of individual families and neighbors animates the social instinct, disperses worry, and sharpens the senses; but such cannot be expected where begrudged trips to town and infrequent

outings are the rule. The faculties and emotions, which are necessarily dulled by monotonous routine, physical toil, and inactivity, require cultivation in order to make them responsive. Play is indispensable to man and beast. Farm life can be expanded and mellowed by the play and freedom which out-of-door recreations yield. Why not enjoy them before work, worry, and age deprive us of the capacity of spirited, joyful living? Children are all more or less destined to receive erroneous ideas in regard to pleasure. Some of them have it knocked out of them by uncomprehensive seniors until they, in turn, bring up their offspring in righteous scorn of what is known as enjoyment. A few of them, however, soon arrive at a rebellious state of mind toward restraints for which they can find no logical justification. Such as these grow up to take their desert with splendid defiance, whenever it most pleases them. They are the people who have kept their souls alive, and who understand happiness. Many a woman on the farm has become accustomed to going through life without any prospect of desert. Her isolation and overwork have tended to produce in her a quiet submissiveness to conditions which allow of no time for spontaneous happiness. Yet the woman's happiness on the farm is one of the great essentials to rural progress; therefore, let the farmer husband look to it that his wife is afforded time, energy, and health for happiness, and let neither of them be so busy getting ready to live that they never have time really to begin. As soon as the farmer realizes that the stock on the place and the products of the farm are not the only things to understand, and that he cannot be successful unless his wife is made sufficiently comfortable and contented to want to stay there, he will take steps to conserve her energies that she will have more time to make herself really more companionable to him. Among the more valuable appliances recently brought within reach of farmers' wives is some variety of oil engine, also water motors. These engines will pump water for all domestic purposes, and can be used to operate the separator and churn, and even the washing machine. Improvements such as these are within the reach of almost every modern farmer, and they will be a more practical help in solving his domestic perplexities than he may at first realise. In this way he will find that all the members of his household have greater and better health wherewith to enjoy life. There is also a great deal of pleasure to be had by allowing the young members of the family to invite their companions to the home, where, with the aid of a musical instrument, such as a piano or organ, they can indulge in music and singing, and spend many happy hours in this way, to the benefit of all that are present in the home. The more we try to advance the social, happy life in our homes and on our farms, the more chance we have of keeping the members of our families with us, and they in turn will take a greater interest in the farm life of which they form a part." Mr. E. J. Herbert entirely agreed with Mr. Smith's views on the subject. A farmer's wife often spent a life of drudgery, but there was no necessity for it. One matter, however, that he had noticed was not dealt with in the paper. Many farmers had very comfortable homes, nicely furnished, &c., but in his opinion not enough attention was given to the kitchen, in which the housewife spent so much of her time. The kitchen should be as well fitted and ventilated as any room in the house. Mr. Sleep said a great many farmers had an ambition to make a competence and then retire to town life. Country life could be made very comfortable and enjoyable if only people went the right way about it. Mr. R. D. Nicholls thought there was a tendency among the young people on the farms to-day to spend no time in amusement and recreation. In the early days the old pioneers of the district, while working harder, still had more enjoyable times than the present generation of young people. Farm life tended to muscular development, and fine physique was often found among the young men on the farms, but very little culture. In his opinion, as farm life developed the physique, so social intercourse tended to develop the mind.

Salisbury, November 5.

PRESENT.—Messrs. Moss (chair), McNicol, Tate, Frost, James, Shepherdson, Hooper Short, Urlwin, T. Judd, Neal, Powell, Hooper, and Jenkins.

THE BREEDING OF LAMBS FOR MARKET, &c.—The paper on this subject which appeared on page 297 of the October issue was read. In discussing the matter, Mr. Neal said crossbred ewes were much hardier than the Merinos; they also produced better lambs for freezing. Mr. Frost had sown oats and barley without manure early in the season, it had yielded good feed, and he now intended cutting half the remainder for hay and stripping the other half. Mr. Patterson believed in cutting the farm into small paddocks, and always allowed the feed to obtain a good start before he put stock on it. For sowing early feed in this district it was necessary to have early rains to enable the ground to be worked.

Mr. Moss advocated heavier manuring. Mr. McNicol mentioned a case where a 40-acre block had last season been put under peas with the exception of a small strip, which had carried oats. Six hundred wethers were put on the crop, and they cleaned it out. During May of this year, the paddock was ploughed up and sown with King's Early wheat. The wheat was now showing an excellent crop, and that portion of it on the area which had previously been under peas was somewhat better than that on the land on which oats were grown.

YORKE PENINSULA DISTRICT.

(TO BUTE.)

Moonta, November 11.

(Average annual rainfall, 15in.)

PRESENT.—Messrs. W. B. Stacey (chair), C. H., and E. Nankivell, T. R. Luke, J. Bowden, H. Fuss, P. Ford, A. B. Fergusson, L. Howlett, W. F. Ortloff, T. Laidlaw (Hon. Sec.), and two visitors.

HAYMAKING.—Mr. C. Nankivell read the following paper:—"Haymaking is one of the most important operations connected with farming, as it is concerned with the preserving of food for the sustenance of the stock throughout the year. The primary essential is to cut and preserve it to conserve the most nutriment. It should not be cut too green, or it is likely to have a scouring action on livestock. The highest quality will be secured if it is cut when the grain is of full size but still in the milky stage. Ears, stalk, and flag will then prove equally nutritious, and if properly cured the chaff will show a nice green color and possess a small quantity of shrivelled grain, which are the usual commercial standards. If the crop is allowed to over ripen the nourishment goes into the head. It is better for the stock that this should be distributed throughout the plant. I believe in close mowing. When binding, the twine should be kept fairly well down and tied as tightly as possible. This makes the sheaves better to handle and means a saving in labor. I believe in stooking as soon as the crop is cut, in small stooks, which should be left for from 10 to 14 days before stacking. The best hay wheats are Marshall's No. 3, Gluyas, and Baroota Wonder." Mr. A. B. Fergusson believed in cutting his cleanest and best crop for hay. Many farmers cut dirty and self-sown crops, thereby spreading weeds over their land. He preferred King's Early wheat and Cape oats mixed—1 bush. of oats cross-drilled with three-quarters of a bushel of wheat and 50lbs. of super. both ways. The Cape oats were sweeter than Algerian. The hay should lie for between half a day and a day before being put into small stooks, it would then be ready for carting sooner. If hay were cut on the green side horses were more likely to scour if it were fed to them when it was new. Mr. W. B. Stacey believed in cutting wheaten hay shortly after the flower had dropped, and stooking directly after it was cut. All the sap was retained in the stalk, and better color chaff, which commanded a higher price than that cut when the wheat was full, was secured. Oats should be left until nearly ripe. Members preferred King's Early, Marshall's No. 3, and Gluyas to Le Huguenot and similar wheats for hay. Mr. Brinkworth had drilled in 50lbs. of guano before fallowing. He considered that the manure when worked with the soil would be thoroughly mixed, and when sowing he would drill from 50lbs. to 75lbs. more of manure. He tried this last year and the crop promised to be the best he had had. He also drilled in some wheat as late as August for greenfeed, and tabled plants 18in. long just out in ear. He generally has greenfeed until the end of the year. Mr. W. F. Ortloff sowed field peas, and believed they were better than oats for the land. They were preferable for fattening lambs, and were useful in stopping the drift on sandhills. Members preferred oats to peas unless on small holdings.

WESTERN DISTRICT.

Coorable, September 28.

PRESENT.—Messrs. A. W. Hardy (chair), Giles, Riddle, W. H. Wheadon, Atkins, Stott, C. Wheadon, Murray, Woodforde, Roberts, Basnett, Underwood, Jackson, Coppins, Gregory, C. Hobbs, Attick, Weston, Cousins, Iles, H. V. Hobbs (Hon. Sec.), and 11 visitors.

ANNUAL CONGRESS.—The following extracts are taken from the report of the Hon. Secretary on the Annual Congress :—"The remarks of Professor Perkins were particularly applicable to the Lower North, but I am convinced that Six-row or Cape barley can be grown relatively successfully here. On inquiry I learnt from some of the West Coast delegates that they find barley stubble very good to burn, it grows thickly and is easily trampled down; this is a consideration with many who are anxious to start fallowing, but desire to get the majority of the roots killed first. Mr. Quinn kindly told me that the fruits most likely to grow here are the almond, peach, nectarine, fig, grape, and pear, and possibly the Japanese plum. He advised grafting peaches on to almond stocks to get better results. We all know that the almond does well here, it does not object to the superabundance of lime in our soil to the extent some fruits will, it also likes thorough drainage, and that our limestone subsoil naturally affords. The Agricultural Bureau is now going ahead by leaps and bounds, and it will continue to do so now that farmers all over the State are seeing the advantage of belonging to such an excellent institution. There are about 140 Branches and over 3,000 members. Farmers have everything to gain by becoming members. It is a great co-operative force by which every member, if he is at all wide awake, helps himself, his fellow member, and his State. It forms a kind of continuation school for the farmer. Through our Agricultural Bureau we are brought in touch with experts and scientific men in every department of the agricultural and horticultural world, in veterinary and every other science that can be of service to the farmer. Any matter that puzzles a member or proves a stumbling-block to him in his daily round on the farm should be brought forward at the meetings and discussed, and, if necessary, an expert reply can be obtained on the subject for that member. There is no limit to the variety of experiments which we could undertake. We should all like to know exactly the relative value of light and heavy dressings of manure, light and heavy sowings of seed, of early and late fallow, of summer ploughing, of harrowing the growing crops, &c., &c., and all these things can be solved with very little trouble if we will all do a share. I would suggest that we appoint an experiment committee and obtain a book in which to keep a careful record of all tests. We should keep a watchful eye for diseases among stock and pests, and report same at once. By doing this we may be the means of preventing great loss among our stock and crops by nipping in the bud some contagious disease. Where there is a strong Branch of the Bureau there will be found the most progressive and successful agriculturists." All agreed that the plan of saving a stack or two of straw to use as feed, was a good one. The Chairman said he thought that perhaps salt would be better than molasses in the straw stack for inland districts, but in a district such as ours, near the sea coast, and where the herbage seemed naturally salty, he would prefer molasses. Most of those present were of the same opinion. Mr. Atkins had tried growing Cape barley, but without much success. Mr. Stott had both Cape and English malting barley growing on his farm and present appearances were in favor of the latter. It certainly seemed earlier than the Cape or Six-row variety. The Chairman's opinion was that the quality of barley grown in this district would not be good enough to command a payable price.

Coorable, October 26.

PRESENT.—Messrs. Kinsley (chair), Wheadon, Riddle, Gregory, Jackson, Murray, C. Hobbs, Grimes, Evans, Fox, H. Hobbs (Hon. Sec.), and one visitor.

SEASON'S PROSPECTS.—The prospects of the season were discussed by members. The general opinion was that crops of this year would be below the average, owing to a deficient rainfall since seeding, hot winds in the spring, and in some parts of the district a plague of grasshoppers and numerous rabbits. It was anticipated that yields would be at least one-third less than last year. Roughly estimated, there was an increased area under crop to the extent of 1,500 acres over the previous year, for which the hundred of Wokata was entirely responsible.

HAY-MAKING.—Mr. Riddle contributed a paper as follows :—"Wheat intended for hay should be sown early and consist of an early variety, otherwise the farmer has not

got his hay carted before it is time to start stripping wheat. Fallow land usually gives a heavier out of hay, just as it gives the highest yield of wheat. Different varieties of wheat suit different districts, and for this district the best hay wheat is Smart's Early, or Clubhead if for home use; but for sale purposes I like King's Early or Huguenot, as the latter grows tall and weighs well. I advise sowing 1 bush. or 1½ bush. of seed, with 60 lbs. or 70 lbs. of super. per acre. The best results are obtained by cross-drilling, using half the amount of super. and seed each way. The right time to cut wheaten hay is about a week after the flower falls; the greater part of the straw is then still green, and there is a fair amount of grain in the head. Hay should always be cut with the binder, as it is much better for handling and chaffing, and there is less waste. Stook the sheaves directly they are cut—this preserves the color. Stooks should be made four sheaves wide; in this way they are not so likely to be damaged by rain as is the case with big round stooks. Hay cut in hot, dry weather should be left in the stook for about 12 to 14 days; in cool, damp weather longer. A lot of hay has been spoilt in this district simply through being carted too soon. For the bottom of the stack I recommend large stones, or failing these, timber. In stacking, the sheaves should be placed with the butts outwards, taking care to keep the middle of the stack about 2 ft. higher than the sides. I believe in doing all the stacking by hand; the same with stooking. Some build the outside rows by hand and fill in the middle with the fork, but if this is done the stack does not settle down evenly, for hand-stacking results in a much firmer stack. Stacks should always be thatched to keep out the weather, and straw is best for this purpose. The little time and trouble will save a lot of hay. Sheaved straw is much better than loose, rough straw. The straw should first be wet in the sheaves and then have the bands cut. Start at the outside and lay a thickness of about 4 in. of straw, thrust thin sticks about 3 ft. long into the roof of the stack about 18 in. apart, taking care that the sticks point slightly upwards; run binder twine from stick to stick, taking a half-hitch around each. Then put on another layer of straw, with a good lap over the first layer; another row of sticks and twine, and so on to the top of the stack. I have never had a sheaf of hay spoiled in the stack when thatched in this way." In reply to questions, Mr. Riddle further said that when sowing wheat and oats mixed for hay a late variety of wheat should be used, and Cape oats put in in preference to Algerian, as the former seemed a little earlier. Oats should not be cut green for hay. Huguenot wheat was, in his opinion, too hard and stiff for good horse feed, and to get a fair crop it seemed necessary to sow at least 1½ bush. to the acre. Clubhead made a hay very acceptable to horses, and they did well on it. He did not think that a heavier dressing of super. would affect the quality of the hay. Leaving it too long before cutting meant losing most of the nutriment of the straw. Long, narrow stooks were more convenient when carting. He recommended, in a season such as this, any farmer who had a good length of stubble after stripping, to cut the straw with the binder and chaff it for feed; but cut it directly after stripping if possible. Musty sheaves, if fed at all, should first be thoroughly dried in the sun and well shaken before being given to stock. Some members favored Marshall's No. 3 for hay, although it was considered a bit too late for this district. White Tuscan did not seem to be a success. Members thought that it required a heavier rainfall. Mr. Kinsley believed that a lot of musty hay was due to the practice of starting the binder too early in the morning and working late at night, when the crop was wet with dew. Mention was made of one hay crop growing in the district that showed very great benefit from an application of stable manure to the land.

Elbow Hill, October 26.

PRESENT.—Messrs. Cooper (chair), E. Wake, A. Chilman, P. Wake, H. Wheeler, H. Wake, C. E. Jacobs, E. Story, F. Wheeler, G. F. Wake (Hon Sec.), and three visitors.

REGISTRATION OF STALLIONS.—Considerable discussion took place on this subject. Mr. Chilman expressed the view that the introduction of a scheme for the compulsory registration of stallions hired for service would be detrimental to the interests of the farmer who bred horses. Horse owners would demand a high fee for service, which would prevent the man of limited means breeding from his mares. He believed it to be advisable to empower veterinary surgeons to reject horses on account of size as well as unsoundness. Members generally were in accord with this view.

Green Patch, October 21.

(Average annual rainfall, 26in.)

PRESENT.—Messrs. F. Gore (chair), E. M. Sage, C. Parker, G. Merchant, T. Freeman, J. Sinclair, sen., J. Sinclair, jun., G. Sinclair, H. Schwardt, A. Murray, C. J. Whillas (Hon. Sec.).

RABBIT DESTRUCTION.—Mr. G. Sinclair read a paper on this subject, in which he stated that in his opinion the cheapest method of getting rid of this pest was to use S.A.P. and pollard. A quarter of a teaspoonful of strychnine sprinkled on to a pint of wheat, which had previously been damped with water, could be placed in a plough furrow, and would be found very satisfactory bait. Dry flour could be sprinkled on to the grain to prevent it sticking together. Where there were a number of burrows a good plan was to drive in the rabbits with the aid of dogs, and place a piece of bagging saturated with water and containing a piece of calcium carbide into the openings, which should then be blocked up. In discussing the subject Mr. Freeman stated that as a result of 19 years' experience he considered pollard and S.A.P., with treacle added, used in a poison cart, the best means of checking the pest. Farmers would have been driven off the West Coast if it had not been for the poison cart. He had tried other poisons, but found the rabbits took the phosphorised pollard the best. He considered that the unoccupied blocks in the district were the main cause of the rabbits being so difficult to deal with, and thought the Vermin Board should do more towards forcing the blockers to destroy the vermin. Members generally agreed with Mr. Freeman on this point. Mr. McFarlane stated that in Victoria the rabbit inspectors had the power, after having given the land-owners ample notice, of putting on men at 8s. per day to destroy the rabbits and charging the owner with cost of same. He thought the South Australian Act should be amended on the same lines. The farmers in this district were doing their utmost to destroy the rabbits, but they were surrounded by unoccupied blocks, upon which practically nothing was being done. Mr. Sage considered $1\frac{1}{2}$ bush. of pollard, $\frac{1}{2}$ bush. of bran, and one tin S.A.P. the best mixture for poisoning, while Mr. Parker favored Gisko. The Hon. Secretary stated that if the Vermin Board enforced simultaneous poisoning throughout the district to the extent of at least 1 bush. of phosphorised pollard each month per square mile for the months of February, March, and April there would then be few rabbits left to do serious damage. He considered S.A.P. too expensive for poisoning to any extent, and thought it better to buy the pure phosphorus. In winter he dogged the rabbits, dug out holes, and fumigated with carbon bisulphide. He found that they took the poison most freely if it were put out after the first rain at the end of the summer. He considered net fences of little use in districts where there was much running water. Both Mr. Sage and Mr. McFarlane had positive proof of rabbits jumping 42in. netting, and all members knew of their jumping 36in. netting. It was generally considered that the rabbits would take the pollard better when sour than when fresh mixed, and that they would take it most readily in the spring after a dry spell.

Green Patch, November 1.

(Average annual rainfall, 26in.)

PRESENT.—Messrs. F. Gore (chairman), A. Porter, G. Merchant, R. Chapman, E. Chapman, J. Sinclair, sen., G. Sinclair, C. Venning, T. Freeman, S. Bailey, T. Murray, D. Murray, C. Dordward, H. Hill, M. McFarlane, C. Parker, C. J. Whillas (Hon. Sec.), and two visitors.

THISTLES.—Mr. R. Chapman tabled a specimen of a thistle which he and some of his neighbors considered should be gazetted a noxious weed. Several members stated that this was plentiful in the hills between Port Lincoln and Tumby Bay, and was considered a fair sheep fodder. It was resolved that the Secretary forward a specimen to the Department of Agriculture for identification.

BERSEEM.—Mr. Porter tabled a splendid bunch of berseem 2ft. 6in. in height. He put in eight acres about the end of last April. Of this the rabbits destroyed seven and a half acres, but he succeeded in keeping them out of a half-acre piece, situated on a deep well-drained black soil flat. This had been ploughed and harrowed, and the seed drilled in at the rate of 20lbs., together with 1cwt. of bone super., per acre. He had already taken three cuts, the half acre producing 7 tons of green feed. It was now ready for the fourth cut, and was a thick, heavy crop 2ft. 6in. in height.

FODDER PLANT.—Mr. Parker reported that he had been trying a new fodder plant, (*Blitum capitatum*), which he thought would be useful in the district. He sowed

some seed in September, 1911. This had grown well through the summer, and was spreading rapidly on his cultivated ground. The plant grew about 2ft. high and stock ate it readily.

COWS GOING BLIND.—Mr. Porter and Mr. Parker each had just lately one cow of their dairy herd go blind suddenly. Messrs. Chapman and Sinclair stated that this complaint had been common with cows in this district for the past 20 years. It did not affect steers. [This trouble was mentioned to the Veterinary Lecturer, Mr. F. E. Place, M.R.C.V.S., B.V.Sc., who states that the blindness referred to is very much akin to some forms of "coasting," and is due to the blood supplied to the eye being very defective in nutriment. It is equally common in working bullocks. Steers feeding only escape as they obtain the essential elements in the food which are not sufficiently plentiful for cows in calf or in milk, or working cattle. As treatment I would recommend bonemeal and salt licks for the cows, and in the two cases mentioned I would dose them with a dram of sulphate of iron and the same quantity of powdered nux vomica, and half a dram of sulphate of quinine in a little molasses and water twice a day for a week, having previously taken two quarts of blood from the jugular vein only once. Bran and oilcake in the feed will also do good.—ED.]

INSPECTION OF CROPS.—Members inspected Mr. Freeman's kale crop, consisting of an area of 70 acres, half put in last autumn and half this. The crop was doing well, and had provided splendid grazing. Members were of the opinion that Mr. Freeman had proved kale to be the most valuable fodder plant tried in the district for the average soil, and many members intend sowing it extensively next year.

Miltalle, October 26.

(Average annual rainfall, 14½ in.)

PRESENT.—Messrs. E. P. Smith (chair), W. G. Smith, J. P., J. W., and E. Story, P. G. Wilson, F. F. Alm, C. E. Searle, A. M. and M. H. Wilson, F. Jacobs, H. R. Jacobs, W. E. Hier (Hon. Sec.), and five visitors.

DESTRUCTION OF RABBITS.—Mr. F. Jacobs initiated a discussion on this subject, in the course of which he stated that he had tried many different way of combating this pest, and had come to the conclusion that trapping was best. Poison could be laid when feed was scarce, but it was a mistake to think that this was all that was necessary, as only a small percentage of the rabbits would be killed in this way. The Chairman advocated united action, and thought that the Vermin Act should be strictly enforced. It was decided to draw up a petition requesting the Vermin Board to take steps in this direction.

Petina, October 19.

(Average annual rainfall, 12½ in.)

PRESENT.—Messrs. W. Penna (chair), D. T. Kenny, A. Kenny, H. Doley, J. H. Wharf, W. G. Lewis, E. Keeley, P. Barnes, O. J. Howard, (Acting Hon. Sec.) and three visitors.

FARM MANAGEMENT.—In a paper on this subject, Mr. D. T. Kenny deprecated a tendency on the part of a large number of farmers in the outlying districts to spend too much time in recreation, and he attributed a number of the failures to this factor.

PLOUGHING.—A good discussion took place on this subject. Mr. Kenny had fallowed a paddock and had turned part of it back on account of the appearance of a weed. The crop on this particular part was very backward. Mr. Wharf had ploughed part of his land twice, and the crop on this was much better than that on the other land. Mr. O'Grady expressed the view that fallowing should be finished before August, and Mr. Wharf considered that on sandy land shallow ploughing tended to prevent drift. Mr. Keeley would commence fallowing as soon as seeding was finished, and plough to a depth of 3 in.

Utera Plains, October 26.

(Average annual rainfall, 14 in.)

PRESENT.—Messrs. P. Sinclair (chair), A. Venning, A. Ramsey, W. Gale, W. Stephens, J. and M. Abbrook, F. Braunack, N. Guidera, W. Lee, G. C. Bilney, H. T., T. C., and H. G. Hornhardt, H. D. Rule, F. H. Haywood, R. Hill (Hon. Sec.), and eight visitors.

CONSERVATION OF FODDER.—The Hon. Secretary read the following paper:—"Farmers

should, while seasons are good, make provision for dry spells. This can be done by stripping the crop and saving the cocky chaff, making straw stacks, &c. During the last period of good seasons, a large percentage of the farmers conserved no surplus feed whatever. The majority of those who used the motor winnowers were no better off than those who used the harvesters. It is at this point that we can see how neglectful we have been. I recommend the header when seasons are good. For the use of this machine the crop should be of a fair length, say 3ft. In a district like this, where the stumps are so bad, farmers can be excused for not putting the binder over any more ground than is absolutely necessary, but it is easy enough for a farmer to cut from 50 to 100 acres every second or third year for heading, according to the quantity of stock kept. The crop intended for this purpose should be cut about a week or 10 days before it is fit for reaping, and it should be tied as close to the butts as possible. It can then be stacked and headed at the farmer's convenience. I prefer the headed straw to straw that is raked up and stacked, as headed straw can be chaffed for the stock without the danger of sticks going through the chaffcutters." A keen discussion followed. Mr. W. Gale said that although he used the motor winnower he preferred the cocky chaff from the hand winnower, as the motor machine threshed the heads and blew the backbones into the chaff—the stock did not care for these. He generally agreed with the writer. Mr. A. Venning thought farmers should pay more attention to the combs of their machines. The use of the header was a good plan, especially when the farmer had his own engine. Mr. Searle (a visitor) was strongly opposed to the use of the harvester, as it wasted all the cocky chaff, and there appeared to him to be several weak points in the machine. Mr. Ramsey said farmers should remember the struggles they encountered during previous dry spells, and that would be sufficient to induce them to gather a portion of their straw each year, no matter how rough the stumps were.

Yadnarie, October 26.

PRESENT.—Messrs. W. L. Brown (chair), J. and F. W. Dreckow, E. C. Kruger, F. W. Jericho, R. H. Parbes, R. B. Deer, C. W. Mowat, B. B. Crosby, S. H. Pearce, A. Preiss. J. J. Deer (Hon. Sec.), and four visitors.

DAM-SINKING.—In a short paper Mr. J. Dreckow said careful attention should be given the selection of a site for a dam, as it was necessary that a good clay bottom should be obtained, or the dam would not hold. Drains should be made according to the body of water they were required to carry, but if they were given a fall of more than 3in. or 4in. to the chain there was a danger of creeks being washed out. If the dam were situated in close proximity to the stables care should be exercised in order to prevent the drainage therefrom soaking into the dam. Wherever practicable it was advisable to draw the water with a pump, in preference to allowing the stock direct access to the water. Members generally agreed with this idea, but thought it unnecessary to grade drains for a small dam. More water would be caught where the fall was greater than that advocated by the writer of the paper.

EASTERN DISTRICT.

(EAST OF MOUNT LOFTY RANGES.)

Monteilth, October 26.

PRESENT.—Messrs. Travers (chair), J. Rowan, J. Rowan, jun., D. McDonald, Wells, Carter, P. Gregory, W. G. Gunn, J. Connell, T. R. Smith, R. G. Major, J. Redding, J. Fletcher, W. J. McCulloch, S. Smith, H. G. Gardner, E. Eldridge, G. Fraser, M. McAuliffe, J. Ferries (Hon. Sec.), and 50 visitors.

IRRIGATION.—The Director of Irrigation (Mr. S. McIntosh) gave an instructive address on this subject. He advocated the perennial system as was practised on the reclaimed Murray swamps, and strongly condemned the basin system of irrigation.

Monarto South. November 21.

PRESENT.—Messrs. G. Patterson (chair), R. E. Anders, A. P. Braendler, J. and H. Frahn, G. Gogol, B. Hoff, H. Hein, A. Harper, G. G. H. Paech, A. Schenscher, F. C. Thiele, E. Tilbrook, J. Daly, C. H. Zeunert, C. F. Altmann (Hon. Sec.), and one visitor.

PEAS.—In a short paper on this subject Mr. Harper stated that while peas were more successfully grown in a cooler climate, it was possible if the land were carefully cleaned, to secure good crops in this district. It was advisable to sow in May, as although there was more likelihood of trouble from frosts the grubs would be less troublesome, the straw of the plants was not so long, and the peas harder. A bushel and a half of seed should be put in together with 2lbs. or 3lbs. of oats or other crop to hold the peas against the wind. When stumpy or rough land was being sown with clean seed it was advisable to put a little cocky chaff with it, as the peas would set down tightly in the drill, and the distributors would not work properly. The crop should be cut before it ripened, and cocking should be done immediately. Peas sown on sand should not be put in until the last week in July or up till the second week in August, 5lbs. of oats and 5lbs. of bonedust or super. being added. Larger dressings of manure would result in the crop being too tender and likely to suffer from hot winds. Members agreed that while this district was not suitable for pea-growing, this crop might pay indirectly by putting the land in better heart. Harvesting would not pay, the best practice being to feed off the crop with sheep.

Morgan. October 26.

(Average annual rainfall, 9in.)

PRESENT.—Messrs. R. Wohling (chair), J. T. Hempel, E. Hausler, R. Wohling, jun., E. Gilgen, O. Hausler, J. Heppner, I. Pope, H. Wohling (Hon. Sec.), and one visitor.

IRRIGATION.—In a short paper on this subject, Mr. E. Gilgen expressed the view that every farmer on the river should have a pumping plant. Three or four square chains of lucerne irrigated with sprinklers, would provide green feed for two cows right through the summer months. A windmill which he had put in had more than paid for itself in one year, in the way of extra return of feed for pigs, horses, and cows.

HAY-HARVESTING.—Mr. O. Hausler contributed a paper dealing with this subject. Land on which hay was to be grown, he said, should be carefully cleared of all sticks and rubbish, which would cause a great deal of trouble in the mower or binder if they were left. Marshall's No. 3 was a suitable variety for hay in this district, Steinwedel was good, but Federation had a tendency to develop a very white straw if left standing too long. Le Huguenot and Indian Runner were preferred by some, and these should be cut just as the bloom had fallen. Wheat for hay should be sown early in the season, in order that it might obtain a good start. An abundance of super. should be provided to force its growth, and cutting should be carried out when it was well in the grain stage. Stooking should be done immediately after cutting, and stacking should not be commenced until the whole crop had been cut. Chaff-cutting was best carried out in the early morning, as the hay was then generally a little damp, and it did not split. The binder was the most suitable means of cutting the crop, as it entailed less waste, and sheaves were more easily handled than loose hay.

Parrakie, October 26.

PRESENT.—Messrs. F. J. Dayman (chair), A. J. Beelitz, H. Deiner, O. Heinze, W. Threadgold, R. F. Brinkley, F. W. Randall, F. W. Gravestocks, A. F. Dayman, J. Temby, jun., C. E. Hammond, R. L. Beddome, R. E. Jose, F. S. Dayman, M. Kildea, N. Good, M. Cooney, T. Willis, A. Heinkel, A. C. Hameister (Hon. Sec.), and five visitors.

HARVESTING.—The following paper was read by Mr. R. L. Beddome:—"There are three methods of harvesting adopted in Australia, viz., the use of (1) the binder and thresher, (2) the combined harvester, (3) the stripper and winnower. The farmer has to decide which of these is best suited to his particular locality and circumstances. (1) The first method—that of reaping the crop with a binder and threshing the grain by means of a steam threshing plant—can be eliminated as impracticable in our district. It has little to recommend it to the farming community of this State, except, perhaps, in the extreme South-East. Our choice, then, is narrowed down to the stripper or the harvester. Both of these machines have staunch advocates, and it is a highly debatable point as to which method is most profitable in mallee farming. The combined harvester, as its name indicates, practically completes in one operation all the work of gathering the grain

ready for market. It thus has an outstanding advantage over the stripper in labor-saving. Most farmers have experienced the difficulty of finding adequate labor at harvest time, and as the use of the harvester renders one much less dependent on that expensive commodity, naturally the machine has many advocates. In our district one man and a team with a 6-ft. harvester should be able to handle, say, 300 acres of crop—barring accidents. On the other hand, the harvester strikes one as being rather too complicated a piece of machinery, and too cumbersome to be worked successfully in our rough mallee country. We are asking rather much of such a machine in expecting it to work at anything like its best in this locality. For one thing, the country is too uneven; difficulties present themselves at once when the machine has to negotiate sandhills and heavy-going with intermittent solid and perhaps stony ground. It is far from simple to regulate the pace of the shake of the sieves, and the strength of blast from the fans, as the horses naturally slow down considerably when drawing the machine over the rises. The blast must, therefore, be increased going up a hill and should be decreased when on the down grade, or probably a lot of wheat will be blown over the sieves. Then the mallee stumps, of which quite a few are still to be encountered in our paddocks, are responsible for a lot of wear and tear to the harvester's mechanism, and will cause it to be cast aside when its lighter and less complex rival, the stripper, is still in good going order. Another drawback to the use of the harvester, though perhaps not of vital importance, is that any grain not properly ripe when harvest work starts is bagged up and is apt to be a source of damage to the sample and to encourage the presence of weevils in the barn amongst the wheat retained for seed and storage. The method of harvesting by means of the stripper or reaping machine has also much to recommend it, especially in new districts. The simplicity of the machine is a decided point in its favor. It is an easy matter to drive a stripper; and as there is very much less chance of mishaps and breakages occurring, much risk of expensive delays is obviated. Another great advantage of the stripper is that its use enables the farmer to save and utilise as much of the cocky chaff as he desires. After the experience of the past season members will no doubt agree that a good stack of cocky chaff is not to be despised, and will gather as much of it as possible this year, and thus save the haystack. Most of our settlers have been obliged to buy chaff at a fancy price this year, and no doubt those who had plenty of 'cocky chaff' saved their pockets to a great extent. I found that my horses worked well and kept in good condition through seeding on cocky chaff, moistened well with molasses and a small ration of bran or pollard mixed in, with a feed of long hay at night. The lighter draught of the stripper, compared with that of the harvester, is another point in its favor, and may compensate for the extra time required for winnowing, by saving considerable time in taking the wheat off. For instance, if a man were short of horseflesh he could get over more country with strippers in the same time; whereas, if he had a horse or two to spare beyond those required for the harvesters, he could utilise them to work two teams a day in a stripper. The drawback to the stripper is, of course, the extra manual labor required in cleaning the wheat; also there is the danger of rain damaging the wheat while in the heap awaiting the winnower. On the whole, looking at the matter from a local standpoint, at any rate, I think the stripper and winnower will be found the best and most economical method of harvesting, more especially in the case of those who have a large area under crop. In dealing with large blocks of wheat, one power winnower and a team of men can handle a very large quantity, and the capital cost of the machinery is very much less than that required to purchase sufficient harvesters to do the work; furthermore, the plant would still be in good order when the harvester would be on the scrap heap. A winnower would still be required on the farm even if all the wheat were taken off with harvesters, and as most farms have an engine in use to drive a chaffcutter, or pump water, &c., the same motor could be utilised to drive the winnower and do all such work. Farmers would be well advised to use the stripper in this district and save their haystacks and their horses." In discussing the subject, Mr. H. Deiner said that the regulation of the blast in the harvester when going up or down hill was simple. The wear and tear of the machine was not greater than that of the motor winnower. Mr. Good favored the use of the harvester, as during the summer it was possible to get into the crop at least three hours earlier than was the case with the stripper. Then it was a difficult matter to secure a suitable floor for the wheat in this district. Mr. A. J. Beelitz, who had used both machines, preferred the harvester on account of the fact that it enabled the farmer to start earlier in the morning, and there was not the waste that was occasioned with the stripper. Mr. A. J. Dayman agreed with this view. Mr. Jose thought the land in this district too rough to admit of the advantageous use of the harvester. The wear and tear would be a heavy item. Mr. Temby, who had gathered his crop last year with harvesters, had come to the conclusion that the land was too rough for the machine.

PROTECTING HAYSTACKS.—In a paper on this subject, Mr. R. F. Brinkley drew attention to the necessity of selecting a fairly level spot on rising ground, free from water-courses, on which to build the stack. A stone platform 6in. above ground at one end, sloping to ground level the other, and raised about 6in. above the sides in the centre, should be provided. This should be coated to a depth of about 1in. with cement. Where the practice of putting a layer of straw on the ground, and building the stack on this, was adopted, there was considerable waste, on account of the straw drawing the moisture from the soil, and thus spoiling the first layer of sheaves. A shed should be constructed over the platform, with a sliding roof placed 20ft. from the ground. Six feet galvanized iron, put 1ft. in the ground and with 9in. bent outwards at the top should be used as a fence to protect the stacks from mice. The iron roof would provide a good catchment, and the water could be run into an underground tank, sunk at least several yards away from the bottom of the stack. A tank of 20,000galls. capacity would be found ample for a 70-ton hay shed. The provision of accommodation as recommended above for hay, should result in a saving of at least 8 tons that would be lost if the stack were placed on straw and thatched. Members generally agreed that it was advisable to adopt the suggestions of the writer of the paper where the means of doing so were available.

Parrakie. November 23.

PRESENT.—Messrs. F. J. Dayman (chair), A. J. Beelitz, N. Deiner, E., O., and A. Heinzl, W. Threadgold, F. W. Randall, F. W. Gravestocks, E. E. Hammond, J. G. Temby, F. S. and A. F. Dayman, M. Kildea, M. J. Cooney, N. J. and S. R. Good, T. Lewis, A. C. Hameister (Hon. Sec.), and four visitors.

FARM HORSES.—This subject was dealt with in the following paper by Mr. F. S. Dayman :—"In selecting a team for the farm we have to consider which is the most suitable horse, the heavy or the medium draught. I prefer the medium draught, which keeps in condition on less feed than is required for the heavier animal. If we take into consideration the general work a horse has to do, we will find that the former will work as well as the latter where sticks, stumps, or worst of all, sandhills are encountered. The medium draught also seems to be more hardy. If a farmer desires to keep a good team he must sell off his old horses, say, at the age of 12; and a horse, if he has been looked after, will sell well at this age. If he requires a young team he must go in for a little breeding, and I have always found that the medium draught mare is the better from which to breed. There is less danger of her slipping her foal and of experiencing trouble in foaling. Some farmers go to a lot of unnecessary trouble in breaking in their young horses. I do not believe in dragging them up by the neck to a post, attaching them to a log, and chasing them around. All this only frightens the horses and makes them timid. A horse should be run into a small yard and bridled; then driven out and taken as quietly as possible. As soon as it has been taught to lead it should be placed between two quiet horses and driven around a little in order to mouth it; then hook the three on to the harrows, afterwards placing the colt in the team. Members were generally agreed that the class of horses referred to in the paper was the one best suited to the requirements of the district. The manner of handling young horses recommended by the writer of the paper was not approved.

HAYMAKING.—The Hon. Secretary read a paper as follows :—"When putting in a crop for hay, it is advisable to sow hay varieties. A wheat that produces an abundance of flag is preferable to a clean strawed sample. It is also better to sow an early wheat, as this allows more time for stacking before later wheats are ready for the stripper or harvester. Much of the quality of hay is lost through its not being cut at the right time, which is just after the bloom is falling. At this stage there is more sugar in the hay and the stock do better on it. The binder is the best means of handling the crop, as it is least wasteful. It also makes it possible to cart and stack in windy weather, which often means a great saving of time. After the hay is cut it can lie a day or so before being stooked if the weather is fine; but if there are any signs of rain it should be stooked at once. The round stooks are the best, about 20 to 25 sheaves being put into each. If well stooked, rain will not hurt the hay. Under no consideration interfere with the stooks after rain; only stand up the fallen sheaves. The time of stacking depends on the weather; but as soon as the knot will break the hay is fit. If hay is left in the paddocks too long it loses in weight and nourishment. Another important point is the building of the stack. Tons of good hay are wasted through stacks being badly built. A haystack should not be built too wide, 5yds. is sufficient, and the sides should never be

higher than the middle. Great care should be taken to see that the hay is perfectly dry before carting. Even the slightest toughness in the centre of the sheaf renders it unfit to be put into the stack. Round corners are preferable. Old mallee posts or logs make a good floor for the stack. The correct method of building is to back up with the butts out, placing the butts of the second row nearly out to the strings on the outside row, and so on, until the centre is filled up. Building in this way makes the stack firm to stand on. When it is being taken down little damage will be done by fowls if a cut is left open, as the heads of the sheaves are nearly all covered. The heart of the stack should be kept well up, especially near the top. At all heights the ends should be higher than the middle, as they settle out and go down later on. If they are not kept higher at the edges whilst being built there is a likelihood of their slipping out. The stack should be wider at the eaves than at the bottom in order that rain may drip clear. When roofing, it is advisable to put the butts out. The roof should consist of a good coat of the best straw available, straightened out and carefully packed, then covered with wire netting. The straw should be mowed and handled in damp weather. If broken down with a chain or harrows it will not run the water off so freely. Do not have weights too heavy on the netting to hold it down, as they are liable to make the stack uneven. Stacks, as a general rule, should be built north and south, for when they are placed in the other direction little sun shines on the south side and there is a tendency for the wheat to germinate in the winter months." Members concurred generally with the views of the Hon. Secretary, but preferred leaving the hay uncut until there was grain in it. Several members thought the stacking method was out of date.

Pinnaroo, November 16.

PRESENT.—MRS. B. L. Harfield (chair), M. Beckwith, A. U. Burman, F. G. Bonnin, H. E. Dibbin, F. H., P. J., and R. Edwards, H. Fewings, H. J. Harfield, L. M. Hannaford, H. C. Hill, W. A. and M. Kelly, H. Ledger, J. Letheby, B. H. Nash, E. H. Parsons, A. I. Reed, C. A. E. Schiller, J. Scales, W. Venning, L. H. Wright, Geo. and W. Wilson, P. H. Jones (Hon. Sec.), and 10 visitors.

NITROGENOUS MANURES.—Mr. W. H. Chappell, M.P.S., supplied a paper as follows:—
 "The subject of manures is far too comprehensive to be dealt with in a paper of this nature, so I propose to confine myself to discussing the important functions of nitrogen and nitrate manures only in the scheme of natural economy. For the figures and analysis I am indebted to papers by Mr. Apin, Registrar of Moonta School of Mines. In beginning, let me give a few words in explanation of the element 'nitrogen.' It is a tasteless, odorless, colorless, inert gas, occupying in bulk about 79 per cent. or four-fifths of the so-called atmosphere. It neither burns nor supports combustion, and although not of itself poisonous, yet animals or plants, when placed in gaseous nitrogen and excluded from the air speedily die of suffocation. Therefore we see that in its natural condition it is absolutely of no use as a plant food, and although it is calculated that there are about 7 tons of available free nitrogen pressing upon each square yard of the earth's surface, yet plant life makes no use whatever of it in its free state, and it is only when it has been converted by nature—either chemically, or in electrical disturbance, or by the aid of the bacteria in the soil—into some of its compounds or 'salts' that it becomes essential to all forms of growth. The term 'salts of nitrogen' is not to be interpreted in the usually accepted sense. In chemistry the various elements of nature possess affinity for some other particular element, and the two are capable of combining together to form other substances, possessing characteristics perhaps entirely different from the two elements which evolved them. These substances we term the 'salts' of the elements from which they sprang. The great stress laid upon the value of these nitrogen salts as plant food has been fully borne out by the reports of the various experimental stations and laboratories of the Continent and America. From an extensive set of field experiments carried out at the Rothamstead Experimental Station in England, using combined nitrate and phosphate manures, the following figures have been proved:—The yield per acre, using the combined manures, was increased from 12bush. to 36bush., whilst by the use of nitrates only the yield per acre was increased from 12bush. to about 23bush. Similar results have been obtained in America, where the yield was increased by 50 per cent. by the judicious addition of nitrogenous manures. Of all natural nitrogenous manures the farmyard variety is the most valuable, and, I suppose, the most widely used. It consists of the solid and liquid excreta of animals, together with the bedding or litter. Its composition varies very considerably. The principal determining factors being—(1) The age of manure; (2) class of food fed to the stock; (3) kind and quality of litter supplied; (4) whether the manure has been

stored in the open or not; (5) length of time and manner of storing. The following analysis shows the general composition of farmyard manure:—

	Per cent.
Water.....	75.42
*Organic matter.....	16.52
Oxide of iron and alumina	0.36
Lime.....	2.28
Magnesia	0.14
Potash	0.48
Soda	0.08
Phosphoric acid	0.44
Sulphuric acid	0.12
Cl.	0.02
CO ₂	1.38
Silica	2.76

Thus we see that farmyard manure contains all the constituents, without exception, which are required to bring plant life to perfection. Its complexity of composition renders it difficult, if not impossible, to imitate it artificially. The solid and liquid excreta differ widely in composition—for, while the former contains principally phosphoric acid, lime, magnesia, and silica, and comparatively little nitrogen, the liquid contains practically no phosphoric acid, but is rich in alkaline salts, urea, and uric acid, which, on decomposing, yield ammonia, which is a nitrogenous compound; therefore, unless the two excreta are mixed a perfect manure is not obtained. Farmyard manure should be kept in heaps, covered with earth, and protected from the lixiviating effects of rainwater. Well fermented manure is more concentrated, and consequently more efficacious than fresh manure. During fermentation a large proportion of the non-nitrogenous organic matter disappears as carbon dioxide and water, whilst the nitrogen is gradually evolved and fixed by the humic acid present. The effect of farmyard manure lasts from 10 to 15 years after its application has ceased. Light land is benefited through the added organic matter, and heavy soil attains a more open texture and is much more easily worked after its application. It is of particular value to the market gardener. The chief remaining form of natural nitrification of the soil is by what is known as 'green manuring,' or the ploughing in of green crops of the leguminous order, such as peas, which are known to add nitrogen to the soil through their relationship to the bacteria contained in the soil. These bacteria are 'certain microscopic organisms existing in many soils, which, given favorable conditions, are capable of fixing nitrogen and rendering it available for plant food. They do this best when living in a state of symbiosis with such plants as the pea and other legumes, symbiosis being a kind of co-operative existence in which the bacteria derives a certain part of its support from the plant, and in return supplies it with nitrogen in an easily assimilable form. Under the heading 'miscellaneous nitrogenous manures' come such substances as seaweed, wooddust, horns and hoofs, dried blood, soot, and sewage, &c.; dried blood being one of the most valuable. It is eagerly sought after by the manufacturers of artificial manures. The chief artificial nitrate manures are the salts of potash, soda, and ammonium. The first two are found as huge deposits in the soil in various parts of the world, notably, India, Chili, and Peru. From the latter country alone over two million tons have been exported to Great Britain. They are chiefly the products of the sewage from large cities. As a quick acting nitrogenous manure probably the best is nitrate of soda. It is said to be without rival as a top dressing for either corn or root crops. It should not be used in large quantities, owing to its tendency to exterminate plants of the leguminous order and to its effect upon the quality of the grain. It can be used with superphosphates, and on account of its great solubility is very useful in dry years. Similar to sod. nit. is ammonium sulphate. It is obtained as a by-product in the destructive distillation of coal and shale and manufacture of coke. It does not act as quickly as nitrate of soda and is not as soluble, but it is to be preferred in a wet season. If used continuously upon soils deficient in lime it will cause sterility on account of acidity. This may be corrected by the addition of lime to the soil. Calcium nitrate and calcium cyanamide, both rank high as artificial manures, but they possess drawbacks that the previously mentioned two do not. The cyanamide gives off a very considerable quantity of heat when mixed with phosphatic manures, whilst calcium nitrate, owing to its property of absorbing moisture from the air, becomes sticky and difficult to handle in the drill. Every ton of wheat taken from the soil takes with it approximately 40lbs. of nitrogen, every ton of oats takes about

*The organic matter, 16.52 per cent., is equivalent to 0.59 per cent. available nitrogen in the form of ammonium sulphate.

45lbs., and every ton of hay about 35lbs., and since the supply of nitrogen, in an available form, is limited, a stage can easily be conceived in which the supply would be almost, if not totally, exhausted. We frequently hear the argument that continuous application of superphosphates tends to rack the land and rob it of its fertility, but the foregoing would seem logically to suggest that, from constant cropping and burning off of the straw the land has become deficient in nitrogen, consequently the yield falls off considerably. Of course, all soils vary greatly in composition, and what is true of one district is not applicable to another. The only way in which we can ascertain the requirements of our soil is by experiment; this means a deal of valuable time, but the result surely justifies its expense. Agriculture has advanced immeasurably since the introduction of artificial manures, and every season brings a batch of new manures for which much is claimed. The farmer who is familiar with the wants and peculiarities of his land will be in a better position to say what manure shall be used than the man who simply follows his neighbors' lead, or places his trust in advertisements."

Sutherlands, October 26.

(Average annual rainfall, 9in.)

PRESENT.—Messrs. Snell (chair), Geyer, Hensler, Thiele, Badge, Dohnt, Mibus, and Twartz (Hon. Sec.).

CHARCOAL BURNING ON THE MURRAY FLATS.—The following paper was read by Mr. J. Badge:—"The reason mallee charcoal is so valuable is because of the suction gas engine plants, which have only been on the market a few years. Retorted charcoal, by the analysis of the State Government shows a fixed carbon content of 79 per cent., while English analyses state that it contains 95 per cent. The charcoal, which is almost pure carbon, combines with oxygen, forms the gas, and the white ash falls to the bottom of the fire-bars or ash-bin, when used in the above plants. At present I am burning four retorts. These are simply constructed of ordinary corrugated iron, consisting of an inner and outer shell, similar to two round tanks, one inside the other, leaving a space between the tanks of 4in. to 5in., which is filled with earth. The roof is made of steel sheet iron in the shape of a cone, which rests on the inner tank or shell. It has two vent holes in the roof for lighting. I place earth to a depth of 3in. or 4in. over the roof to keep it airtight. It has one large door at the bottom and a small door at the top on the opposite side. When the retort is partly filled from the bottom door it can be closed, and the small door on the opposite side used to fill it. Then close that door, get on the roof, open up the two vent holes, procure some chips and bark and a few dry leaves, put them into these vent holes and apply a light, always from the top. There are four or five vent holes at the bottom of the retort to supply the draught. A good fire will be distinguishable by a dirty yellowish-grey smoke coming from the vent holes at the bottom; close down the two vent holes on the roof, then the carbonisation proceeds. Burn for 24 to 30 hours, and when a light sky-blue smoke appears close it down to prevent any air getting into the retort and allow it to cool. Then remove the bottom door and commence bagging. I find that the second growth of mallee is the best for burning. I put between 32cwts. to 2 tons of wood into a retort and get between 13cwts. to 16cwts. out, so with six retorts going 7 tons of charcoal per week should be secured. The present price is £2 15s. on trucks, Sutherland. Two men are able to look after six retorts and do their own carting, providing the timber is within a radius of a mile. Two men at £3 a week each is an expense of £6; a good cutter, equal to 4 tons per day, at 2s. per ton is £2 8s.; two horses and wagon, £1; a total of £9 8s. deducted from £19 5s. leaves the handsome profit of £9 17s. per week. A good piece of charcoal rings like a bell; it is a bad conductor of heat. Most of the big mallee is more or less pithy, and I would put any pithy wood and logs in the centre of the retort and so give them a good burn." Members generally agreed that it would pay the farmer to burn his wood to charcoal before carting it to market.

Walkerie, October 23.

(Average annual rainfall, 9in.)

PRESENT.—Messrs. T. G. Rogers (chair), A. Lewis, J. C. Rowe, W. J. Green, E. J. Burton, C. Promnitz, W. Frahm, R. Stanley, S. Modistach, C. Borroughs, J. Jachman, J. J. Odgers (Hon. Sec.), and one visitor.

CURL LEAF.—Members reported that last season this was very bad on the peaches, but it was not showing this season. Some had sprayed and considered this had prevented the trouble, but other members had done no spraying and yet their trees showed no sign of curl leaf, although they were badly affected last season. It was thought that the heavy winds experienced had caused the trees to be clean.

HAY CROP.—The hay crop was reported as being very poor, and unless rains fell shortly the wheat crop would be likewise. Fallow lands and early wheat were better and would probably yield a good crop.

IRRIGATING APRICOT TREES.—Mr. Green read a paper on this subject, as follows :—“The correct times at which to irrigate apricot trees are as follows —(1) Before the buds burst early in September, as it is essential that the ground should then be in a moist condition to carry the buds through the blossom period. (2) After the fruit has set, say about October 1st, in order to give the spurs and fruit a good start. (3) Whilst the stone is forming late in October or early in November. This should be the heaviest irrigation, for the energy of the tree is taxed to its utmost, and it should be kept nourished if a good sample of fruit is to result. (4) When the stone has formed and set hard early in December, for then the flesh has to be put on, and it is a mistake to irrigate late as it tends to make the fruit sloppy, and it then dries light.” In the discussion, Mr. Borroughs agreed with the statements made in the paper. Last year, owing to the lack of water, the fruit dried thin. The stone grew without the water, but the water gave thickness of fruit. The principal point was to get water at the right time, even if a little less than was necessary had to be taken. Mr. Jachman reported that many buds on his trees this year did not come out into blossom. Mr. Rogers believed in winter irrigation. Mr. Stanley had 12 hours water in May, but he did not see that his trees were any the better for it.

SOUTH AND HILLS DISTRICT.

Blackwood, November 11.

PRESENT.—S. W. Chapman (Cherry Gardens Branch, in chair), W. L. Summers, A. W. Magarey, A. W. Carlos, R. Eglinton, A. A. Magarey, J. Turner, F. Andrews, C. Shearer, G. F. Dall, F. Dall, H. E. Sibley, A. A. Philips, P. H. Williams, A. J. Penno, J. Nicolle. T. Hunter, C. G. Savage, four members Cherry Gardens Branch, and one member from the Longwood Branch.

PRINCIPLES UNDERLYING ORCHARD PRACTICES.—Mr. W. L. Summers read the following paper :—“I propose to deal with a few general aspects of orchard work, with a view to causing us to think *why* we are doing certain things, in the belief that as a result we shall in the future do these things better than we have in the past. Why do we plough, cultivate, harrow, &c. ? To deal with this question in detail would take several evenings. It is absolutely necessary, however, to have some definite reason as to why we cultivate (to use the term in its wider sense), because without this we cannot know how or when to act to secure the best results. Let me refer to a few general principles. The soil must contain not only sufficient water, but also sufficient air for the healthy development of the roots of plants. If either is in excess or deficiency we fail to secure the best results from our work. Within reason—other things being equal—the moisture-holding capacity of the soil increases with the fineness of division of the soil particles. It is therefore necessary in a dry district to work our soils down to a fine tilth, as this will tend to secure the desired proportion of air and moisture therein. If the soil is lumpy we have too much air and not enough moisture ; if the soil is overcharged with water the air is forced out and the plants cannot thrive. Hence the necessity for under-drainage under certain conditions. A well-broken soil is said to retain nearly twice as much moisture as a compact or hard soil of the same characteristics. We should therefore, in a firm setting soil, plough deeply. We must get the moisture into the soil first and then work it in order to retain it during the dry weather. A dry earth mulch over a firm subsoil permits the water from the lower layers to move upwards to the roots of the plants, and at the same time prevents excessive evaporation. Bearing these facts in mind, it naturally follows that the ‘when’ and ‘how’ of cultivation will vary according to the nature of the soil, the climate, the rainfall, and the crop we have to deal with. A careful consideration of the reasons for tillage will enable the grower to do his work in this direction under the best conditions, at the right time, and at the least expense ; but, while we can each profit from our neighbor’s experience in the matter of tillage, we must modify practices according as our conditions vary. Why do we spray our peach trees for the prevention of curl-leaf at one season and our apricots for prevention of shothole at another ? A knowledge of the differences in the life history of different fungi is necessary to enable us to decide when is the best time to spray. It is practically impossible, especially in a large garden, to do all this work at exactly the right time to attain perfect success, but we can get very near it if we know why a particular time is best to spray

to prevent injury by a particular fungus. Take the two I have mentioned. For curl-leaf we spray as soon as the buds show definite signs of movement in the spring, because the spores of the fungus are lodged in the bud scales, and germinate practically as soon as the flowers come. To prevent injury we must have a thin coating of the fungicide on all parts of the tree, so that the roots (this is not the technical term, but conveys what I mean) come into contact with it and perish. If our spraying is delayed through ignorance, neglect, or climatic conditions until after the fungus has obtained entrance into the young leaves, buds, or stems the mischief is done, and later spraying will not cure the trouble. On the other hand, shothole affects the leaves and fruit at a later period, and not only is it correct to spray when the trees are relatively more advanced, but as the disease spreads over the surface of the fruit it can be checked by a late spraying, and, provided it has not advanced too far, the damage already done may be to a large extent remedied. The mildews on vines and roses are also surface workers, and preventive measures are based on the knowledge of this fact. Why do we prune our trees? Because we know that if left to nature they would not produce either in quantity or quality profitable returns. Nature's object and man's in the matter of fruit-production differ, and it is therefore necessary for us to control nature to work in our way. Before we can prune our trees successfully we must know something about the habit of growth and the nature of the fruit-bearing wood of the different kinds of trees. We must further study the different varieties of the same class of tree; the effect of difference in soil and climate, and so on. A knowledge of the characteristics, habits, and requirements of the different varieties is necessary to enable us to determine which suit our particular conditions and objects, and the absence of this knowledge is the cause of some of the most costly mistakes of the fruitgrower. In this particular point we can and should derive much profit from the experiences of other growers. As a final instance let me mention the necessity for thorough spraying early in the season for codlin moth. Numerous experiments have shown that most of the first brood enter in or near the eye of the fruit, and if we are to prevent their entry this portion must be coated with the spray in order to poison the young caterpillar. Better results would be obtained from one thorough spraying just about the time the petals have all fallen than from three or more later sprayings if the first is omitted. Bear in mind that every caterpillar that escapes out of the first brood means an apple or pear lost, and probably half a dozen second brood caterpillars to contend with. Keeping this in view the necessity for thoroughness in the first spraying will be readily appreciated. My paper may be somewhat general in its scope, but my object at this first meeting of the Bureau is to emphasize the necessity for having at least some idea of the 'whyfor' of our work before we do it.'

Cherry Gardens, October 22.

(Average annual rainfall, 35.3in.)

PRESENT.—Messrs. S. W. Chapman (chair), C. Lewis, C. Ricks, T. Jacobs, H. Jacobs, J. Brumby, G. Hicks, A. R. Stone, H. Lewis, T. Jacobs, jun., J. Lewis, J. Mildwater, J. Tozer, E. Broadbent, S. H. Curnow (Hon. Sec.).
